Extensive venous hemorrhage during removal of an organ or a tumor cannot ordinarily be stopped with clamps and requires gauze packs however, the removal of these packs may start new bleeding. Gelatin sponge needs not be removed which obviates the danger of secondary hemorrhage. Up to this time extensive abdominal resections could be done safely only when unlimited amounts of blood were available for replacement of the blood lost during the operation. Gelatin sponge may help to reduce such losses and thus surgeons in places where unlimited amounts of blood are unavailable may now attack problems they have avoided in the past. Liver surgery will be helped greatly by the new material as will work on the bile ducts or the pancreas. Gelatin sponge will be of value in injuries of the portal vein in neurosurgery for bleeding from the dural sinuses in the skull technique mentioned in the animal studies for the repair of arterial wounds and for patches for the repair of arterial wounds.

As to the mode of action the authors believe that the gelatin sponge acts as a framework for the clot and is finally absorbed. They have not been able to establish what effect if any preliminary wetting of the sponge with thrombin has on its efficacy but they recommend the use of thrombin with the sponge in clinical cases.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Heublein, G. W.: Some Observations Concerning the Hypophyseal Fossa. *Am. J. Roentg.* 1946 50 299

The pituitary fossa of 100 apparently normal young adult soldiers was measured. Its average anteroposterior diameter was found to be 10.66 mm and its average depth 8.30 mm. The largest fossa measured 13 by 9 mm, and the smallest 8 by 5 mm. This agreed closely with the measurements reported by Kornblum.

The average size of the fossa in 6 cases of pituitary adenoma was 23 by 17 mm.

Various normal anatomical variations of the sellar configuration are discussed. The shape and the calcium content of the dorsum sellae are influenced by (among other factors) the basilar sinus (described by Batson and Kornblum). The sphenoparietal sinus or sinus of Bercet—another venous sinus of importance in the reading of roentgenographs of the sella—may be mistaken for an enlarged channel of the middle meningeal artery. Other vascular channels may simulate fractures through the sella.

Intrasellar calcium deposits are not necessarily of clinical significance but suprasellar calcifications (above the diaphragma sellae) raise the suspicion of Rathke's pouch tumor or other pathological changes.

Case descriptions illustrate sellar changes caused by various pathological conditions. Extreme calcification of the petroclinoid ligaments was caused by a parathyroid tumor. Various changes in shape and size of the sella were caused by pituitary adenomas in 6 instances. They were associated with restricted visual fields. Choked discs were absent, however. A

malignant chromophobe adenoma of the pituitary gland caused intrasellar as well as perisellar changes. An enlarged third ventricle (caused by a large pituitary adenoma) flattened the clinoid processes from above and caused "cupping" of the upper superior margin of the dorsum sellae. Similar changes were caused by a narrowing of the aqueduct with consequent third ventricle enlargement due to ependymitis in one case and due to a large frontal cystic astrocytoma in another instance. (There was no direct influence of the tumor on the sella.) A large parasellar bone erosion was caused by a lymphoepithelioma (nasopharyngioma). Erosion of the sella by metastatic tumor was seen only in 1 of 360 cases of malignant disease treated in the radiotherapy department of the Percy Jones General and Convalescent Hospital in 1944 although 2.9 per cent of these cases had evidence of tumor metastases. In this single case the etiology was multiple myeloma.

Aneurysms of the circle of Willis may cause sellar deformities. Usually however they are recognized by their calcium content (to be distinguished from vascular sclerosis without aneurysm) or by means of angiography.

A pitfall in the diagnosis of sellar erosion is decalcification due to pulsation of the brain transmitted to the sella through the basilar sinus, to scissile atrophy to minute basophilic adenomas, and possibly due to a persistent rest of notochord, the so-called physaliform ectodermoma. A faulty roentgenographic technique may reveal restitution of the sella following deep roentgen therapy whereas correct roentgenographs will fail to show changes.

GERHART S. SCHWARTZ, M.D.

Pendergrass, E. P., and Perryman, C. R.: Porencephaly. *Am. J. Roentg.* 1946, 56 441

According to the authors, porencephaly is the end point of many disease processes. It is usually defined as a defect communicating with the ventricles or separated from them by a layer of brain tissue, and covered on the outside by the arachnoid. This condition must be considered in the differential diagnosis of mass or contracting lesions involving the brain. Occasionally it is confused with cystic lesions. Encephalography or ventriculography is necessary to establish the diagnosis of the condition. Roentgenologically the types of porencephaly have been classified as lobe, interlobe and hemisphere.

In the series of 29 cases studied, the average age of the patients was 16 years, the oldest being 34 years and the youngest, 9 months. The duration of symptoms varied from 3 months to lifetime (30 years).

Most of the patients (16) sought medical attention because of epileptic attacks, which usually had been preceded for several years by other symptoms such as weakness of an extremity, strabismus, or mental retardation. Others complained of headache, poor

Fig. (Heublein) Characteristic appearance of the hypophyseal fossa in patient with pituitary adenoma. The thinned and apparently elongated dorsum sellae is shown by the arrow.

memory irritability sluggishness and excitability. Sixteen of the patients in the series had paresis of one or two extremities and 2 of these had facial paralysis as well.

Atrophy or hypodevelopment of one half of the body or the involved extremity was present in those who had had paralysis since early childhood. Occasionally anesthesia was present. Papilledema was present in 3 patients. Four patients had homonymous hemianopsia and bitemporal hemianopsia. Peripheral constriction of the visual fields was noted in one patient. The symptoms were dependent to a large extent upon the location of the lesion. Unilateral change in thickness of the skull was the most common observation in the conventional roentgenograms of patients with porencephaly. Generalized or localized thinning was most frequently present, and unilateral thickening of the vault was less often demonstrable. Asymmetry of the vault was also occasionally observed. Calcification similar to that in malignant gliomas was found in one instance.

Pendergrass, E. P., and Perryman G. R.: Optochiasmatic Arachnoiditis. *Am J Roentg* 1946 56: 279

Ten cases of optochiasmatic arachnoiditis are reported in which the pneumoencephalograms showed incomplete filling and distortion or blurring of the cisterna chiasmatica and/or of the neighboring cisternae interpeduncularis and pontis.

Five patients had visual disturbances and optic nerve atrophies. Operation revealed arachnoiditis involving the chiasma in 4 of them (acute in nature in 1 instance) and a small suprasellar meningioma in 1 patient. None of these showed sellar changes.

The other 5 patients had no eye symptoms or changes. Of these 4 suffered from epileptic convulsions and 1 displayed post-traumatic headaches and weakness in the right arm and shoulder. Craniotomy

c (Legend below)

performed in 1 instance showed a microscopically fresh blood clot. In this group the encephalogram showed a decrease in the number of subarachnoid pathways in addition to cisternal changes. In some of the latter cases the escape of cerebrospinal fluid through the foramina of Magendie and Luschka was apparently interfered with by arachnoid adhesions causing dilatation of the ventricles.

The authors conclude that a careful pneumoencephalographic study of the cisternae will lead to the diagnosis of perichiasmatic arachnoiditis more frequently than is generally anticipated.

Fig. 14 (Pendergrass and Perryman) a, The lateral encephalogram demonstrates cisternal adhesions, b shows a

generalized obscuring of the cisternae and c, shows a variation in the size and number of cortical pathways.

cause of the reaction, and according to the other allergy to liberated (decomposition) toxins is the cause. The author noted that, in addition to his own cases, there were 5 instances in which the radiation had been directed to the trunk over an area in which the red bone marrow was affected. He concludes that at least in his cases allergy was the causative factor but that a hypersusceptibility of the bone marrow to radiation must have pre-existed and that had led to the thrombopenia.

GERRHART S. SCHWARTZ, M.D.

Piemonte, M.: *Histopathogenetic Considerations of Radionecrosis (Considerazioni istopatogenetiche sulla radionecrosi)* *Radial med.*, Milano 9, 1946 3 9

Late radionecrosis is well known in its clinical aspect today the divergencies and uncertainties beginning when one passes from the clinical picture to the pathogenetic interpretation. There are those who attribute its cause to arterial and arteriolar lesions above all, productive endarteritis those who attribute it to a fundamental capillary lesion those who believe in an injurious action by the radiations on the nervous vasomotor apparatus and therefore, in ultimate analysis, again to an action on the circulation although it is indirect. Others believe it is due to technical error, overdosage but in this case one must still explain how the lesion is initiated. Others speak of an elective caustic action by the radiations, giving importance also to collectors such as trauma and infection. Ewing has a similar theory but calls attention to the contemporaneous vascular lesions.

Bjorne Dahl recently proposed a new interpretation concluding that the epidermal cells and piliferous follicles are destroyed by the radiations which also damage the connective tissue and the capillaries and induce a paralysis in the capacity of these elements to repair and proliferate. Secondly when the epidermis is separated one has a vascular reaction which reaches its maximum in the corium, where one observes an imposing capillary dilatation with the formation of an edema in contrast. This edema blocks the blood circulation of the denuded connective tissue and therefore leads to mortification by asphyxia. The necrosis can therefore deepen by regularly bringing every new layer of tissue which becomes necrotic to the formation of edema and to the obstruction of the circulation in a deeper layer. In this way one establishes a vicious circle which is only interrupted when the connective tissue and vessels have recovered their capacity to form granulation tissue.

The author studied the histology of late radionecrosis in 27 cases to see if one could discover elements for orientation in the microscopic pictures of the lesions for the pathogenetic interpretation of the process. He believes that the beginning of radionecrosis is to be attributed to phenomena of vascular thrombosis which manifest themselves consequently by lesions determined by the radiations in the walls of the blood vessels.

The author feels that indubitably the blood vessels are among the most radiosensitive elements and that by consequence of radiation even in a technically correct manner the muscular layer always presents regressive phenomena and the intima productive phenomena. The radiations therefore come to injure the most important functional elements in the vascular wall (the muscular) from which contractility is derived and the intima which assures normal canalization. He describes the histological attempts at repair of this process in the vascular wall and concludes that the result of all this is a slowing down of the circulation in the vessels irradiated. In this connection, an injury of any nature which comes to act on a vessel so anatomically altered can with ease lead to the formation of a thrombus with sudden interruption of the blood supply to the vascular territory situated beneath it.

The author also states that stabilization of a sufficient collateral circulation is not permitted because all the vessels of the irradiated area present similar lesions, and that not even the cells of the tissue irradiated, which is deprived in all or in part of its circulation, are in their best condition of vitality and resistance.

This interpretation of radionecrosis explains the many particulars of the process—the reasons for the clean demarcation, clinical or histological, of the necrotic focus which remains a focus of ischemic necrosis almost resembling an infarct. All of the zone which depends for its blood supply from the vessel or vessels thrombosed not receiving a sufficient supply from the collateral circulation because of the vascular alterations of the same coexistent nature, must be a victim of regressive phenomena while the surrounding tissue demarcates it cleanly.

G. ALBIN LEVA, M.D.

RADIUM

Caceres, E.: *Treatment of Cutaneous Hemangioma with Radium.* *Am J Roentg* 94, 56 5 3.

The present article is based on a study of 66 cases of hemangioma treated with radium at the Chicago Tumor Institute.

As a rule, hemangioma increases in size at a slower or faster rate during infancy. For this reason and since radiosensitivity is greatest early in life treatment should be instituted within the first 6 months after birth. If there is a rapid increase in size or beginning ulceration treatment of the hemangioma must be given immediately even during the first weeks of life.

Of the various methods of treatment that can be used the application of radium is believed to be the most satisfactory. The author limits his discussion to the technique and dosage with (1) filtered contact radium and (2) filtered radium at a distance (mold plaque). The different types of radium applicators used at the Chicago Tumor Institute are briefly reviewed and the approximate dose with each is indicated.

The final result was excellent in 49 cases (74%) satisfactory in 13 cases (20%) and unsatisfactory in only 4 cases (6%).

Some photographs taken before treatment and from 7 months to 3 years and 9 months after treatment are presented for the purpose of illustration.

Taylor H. C. Jr. and Twombly G. H.: Cancer of the Cervix: A Study of the Effect of Interstitial Radon Needles as Compared with Roentgen Therapy Given through Intravaginal Cones. *Am J Roentg* 1946 56 513

In a former report from the Memorial Hospital New York New York the effect of the massive and divided roentgen irradiation on the five year results of carcinoma of the cervix was analyzed. The massive irradiation was carried out by administering 750 roentgens at a single treatment to each of 4 pelvic fields, with 200 kilovolts and 0.5 mm of copper at 50 cm. skin target distance. In the divided irradiation 12 treatments of 200 roentgens each were given to each of 6 pelvic fields, with 200 kilovolts 0.5 mm of copper at 70 cm. skin target distance. Both methods were supplemented with the same type of radium application i.e. 2 intracervical capsules delivering 3,000 mc. hr. and 1 vaginal bomb delivering 1,500 mc. hr. The five year cures amounted to 30 per cent and 36 per cent respectively proving that the divided dose technique of external roentgen irradiation has certain advantages over the massive dose technique.

In the present report this study is being carried one step further. All cases of cancer of the cervix examined during the period from 1943 to 1944 were divided into two equal and comparable groups. One group was treated by replacing the vaginal bomb (but not the intracervical capsules) with intra vaginal roentgen therapy and the other by replacing it with interstitial radon needles which were introduced directly into the parametria through the vaginal vault. The external roentgen was given in both instances with the divided dose technique.

In the first group the intravaginal roentgen therapy was carried out with 150 kilovolts 3 mm. aluminum, at 35 cm skin target distance. Special lead-lined brass cones were used which were inserted by means of an obturator into the vaginal canal with the patient's legs in stirrups. In the typical plan the intravaginal treatment was given 3 times a week during the course of the external roentgen irradiation and before the intracervical application of the radium. Three fields were used: one (4 cm. in diameter) directly to the cervix, and one each (3 cm. in diameter) to each parametrium through the lateral vaginal fornices at an angle of 30 degrees from the long axis of the body. The dose on the cervix amounted to 4 exposures of 500 roentgens in air (total 2,000 roentgens) and on each parametrium to 4 exposures of 750 roentgens in air (total 3,000

roentgens). Not infrequently the typical plan could not be followed. In such instances adjustments based on individual requirements were made.

In the second group the interstitial radon needles were inserted at the time of the intracervical radium application (consisting in this instance of a radon tandem) which as a rule, was 2 weeks after the completion of the external roentgen irradiation. The plan of Nolan and Quimby was followed, which is described in detail. The intracervical tandem and the parametrial needles were left *in situ* until a total dose of 6,000 mc. hr., 3,000 mc. hr. from the tandem and 3,000 mc. hr. from the needles had been delivered.

Although the time of observation was too short (from 9 to 34 months) the superiority of the first method over that of the second cannot be doubted. Thus, the percentage of cases apparently free of cancer when intravaginal roentgen therapy was applied was 48 (54 of 113 cases) whereas with interstitial needles it was only 26 (26 of 94 cases). Furthermore, the patients treated with needles had more severe immediate reactions (diarrhea, dysuria, bleeding) and a larger incidence of late sequelae (stricture, fistula) than did those treated with intravaginal roentgen therapy.

The conclusion is reached that the use of interstitial radon needles in cancer of the cervix is ineffective and dangerous. The intravaginal roentgen therapy in this respect, seems to have a definite advantage, but one should wait for the 5 year results before expressing an opinion also on the relative value as compared to that of the vaginal radium bomb.

T. LEUCOTIA, M.D.

Biomfield G. W. and Spiers, F. W.: Dose Measurement in Beta Ray Therapy. *Brit J Radiol* 1946 19 349.

The early use of beta ray plaques was largely on an empirical basis, since the biological effect was not directly proportional to the ratio of milligrams of radium to the area in square centimeters. The present improved construction of the plaques plus standardization of the determination of the beta ray output of the individual plaques should place this form of therapy on a more exact basis.

The authors have calibrated 2 plaques by means of a specially constructed ionization chamber. The chamber was standardized by calculation of the capacity and the volume and by conversion of the unit into a 7 ray chamber then by a known quantity of radium determining the capacity and volume. A factor of 55 (capacity/volume) was thought to be the best obtained for conversion of the potential change due to beta ray ionization to c.s.u./c.c. (roentgens). Plaque LGI 20 containing 20.4 mgm. of radium distributed in a 4 sq. cm. area with 0.10 mm. of monel filter had an aluminum H.V.L. of 0.43 mm. and a surface dose rate of 4450 r/hr. Plaque LGI 30 containing 31.0 mgm. of radium distributed in a 6 sq. cm. area with 0.10 mm. of monel filter had a H.V.L. of 0.55 mm. of aluminum and a surface dose rate of

4700 r/hr. The addition of 0.03 mm. of aluminum filter to plaque LGI 20 reduced the dose rate to 4550 r/min. and increased the H.V.L. to 0.33 mm. of aluminum, which indicates the extreme sensitivity of beta ray plaques to filtration. The γ rays contribute only from 3 to 4 per cent of the total dose rate.

The relative fall in dose rate with increase in distance between the plaque and the phantom is considerably less than predicted from the inverse square law. This is thought to be due to the oblique filtration effect and must be taken into account in the application of plaques to certain anatomical sites.

The beta ray dosage from plaque LGI 20 was measured independently by G. J. Neary at Mount Vernon Hospital with the apparatus which he had developed. (*British Empire Cancer Campaign Report*, 1943 and *Br J Radiol* 1946 19: 357) The results were in excellent agreement with the values obtained by the authors at distances greater than 1.0 mm. At shorter distances it was thought the differences observed were due to the difference in the construction of the chambers. Smereker and Juris (*Strahlentherapie*, 1935 11: 327) report values more than 50 per cent higher than the author's. However the former standardized their chamber with 9-12 k.v. greus rays having approximately the same H.V.L. as the plaques. Such a calibration is questioned due to the extreme difference in energies of the x rays and the beta radiation.

If a plaque is used as a "bomb" the surface dose and the field distribution is considerably improved by the addition of a 1.0 mm. lead elliptical "reflector." The surface dosage however is no greater than one would expect if the same quantity of radium were distributed in a plaque of the same (large) surface area. This method of treatment ("bomb") while more convenient, is no more economical in radium.

The depth dose curve (in water) of beta radiation corresponds approximately to 25 k.v. greus rays. The H.V.L. is 1.3 mm. of water.

Small rodent ulcers are first curetted, then given a surface dose of 7000 r (2 mm. depth dose of 2500 r) at a single seance. Portwine stains are given 1000 r at 2 or 4 week intervals for a total of 3000 r. Special mention is made of this form of therapy for early superficial rodent ulcers of the inner canthus overlying the lacrimal sac. Adequate dosage can be administered to the ulcer with little or no damage to the lacrimal apparatus. Recurrent rodent ulcers, skin nodules from carcinoma of the breast, and cavernous angiomas are considered too deep for this form of therapy.

The beta-ray plaque is of value in the treatment of superficial lesions. Any lesion requiring more than a 30 per cent depth dose at a depth of 0.25 cm. should be treated by some other method.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Imperati, L., D'Errico G and Ruggiero A.: The Study of Operative Trauma as a Factor in the Production of Shock (Ricerche sul trauma operatorio quale fattore di squasso) *Gior ital chir.*, 1946 3 365

A study of hemodynamic changes following operative trauma in 20 patients brings the authors to the following conclusions

A marked fall of the systolic pressure indicates postoperative shock but a normal or increased systolic pressure does not exclude the presence of compensated shock. A fall of the differential pressure and of the oscillometric index serves as a sign of latent or compensated shock. Differential pressure expresses the energy of the contraction of the heart with peripheral resistance on one hand and contractility of the blood vessels on the other. A fall of the venous pressure is an early sign of shock especially of compensated shock, and particularly if a sharp fall of the systolic pressure takes place. On the other hand a fall of the differential pressure and of the oscillometric index reveals the presence of latent shock.

The author applies the term compensated or latent shock to impending shock.

An accelerated absorption by operated patients of an intradermal wheal produced by the injection of 0.2 c.c. of saline solution is related to an increased permeability of the capillaries and to dehydration of the tissues.

JOSEPH K. NARAT M.D.

Macfarlane R. G and Pilling J.: Observations on Fibrinolysis: Plasminogen Plasmin and Antiplasmin Content of Human Blood *Lancet* London, 1946, 2 562

The clots formed by normal whole blood or by recalcified citrated or oxalated plasma will remain intact in their own serum for days, or even weeks if bacterial growth is prevented. Under certain circumstances, however this stability is lost, so that soon after coagulation they break up and disappear. This phenomenon called "fibrinolysis" has been, until recently mainly of academic interest now there are indications that it may prove to be a manifestation of a fundamental physiological process.

Fibrinolysis has been produced experimentally in dogs by hepatectomy and peptone shock, and by treatment of plasma with chloroform *in vitro*. The latter was considered as being formed from the digestion of fibrin by the proteolytic action of thrombin. Some observers however think that another enzyme related to trypsin is responsible for the reaction. Still others consider it an enzyme associated with the globulin of the plasma, and suggested the name "plasmin." "plasminogen" is the name given

to its inactive precursor and in the familiar culture filtrates of certain strains of *Bacillus hemolyticus* streptococci streptokinase has been ascribed to the bacterial activator.

A fourth component however has been added to these, inasmuch as normal plasma or serum contains an antiproteolytic factor associated with the albumin fraction. It is probably concerned with the absence of fibrinolysis in normal blood and has been designated antiplasmin. The following schematic diagram shows the interrelation of the components

The recognition of these components of a proteolytic system existing in normal blood greatly facilitates an approach to the problem of spontaneous fibrinolysis in man. It is most probable that the disappearance of fibrin in blood taken after sudden death (Lundin 1936) trauma (Macfarlane, 1937) or burns and hemorrhage (Tagnon *et al* 1946) is due to the activation of this system.

The possible significance of such a process becomes the more apparent when it is realized that the plasminogen of normal blood is of a potential activity sufficient to destroy the total fibrinogen of the body in a few minutes and the more interesting since it is apparently associated with the problem of latent shock. Further investigation is desirable, and might be divided into studies of three aspects of the problem: first the interaction of the plasma factors culminating in fibrinolysis secondly the nature of the physiological process that activates the proteolytic system and thirdly the effect on the living in the blood stream.

The experimental technique for the quantitative assay of plasmin is described and the interrelations of plasminogen antiplasmin and plasmin are recorded in table form.

From the experiments it appears that normal plasma contains at least three factors concerned in fibrinolysis. In the globulin fraction is a certain amount of active plasmin, and a further quantity of its precursor plasminogen. It might be argued that the activity observed in this fraction was induced by the technique of separation but, since it is lost on recombination with albumin it is reasonable to suppose that this proportion of plasmin exists in normal blood in combination with the antiplasmin of the albumin fraction. If this is so the combination is a

loose one, being broken by fractionation. Moreover if the plasmin content of plasma is for any reason increased, fibrinolytic activity first becomes apparent in the higher dilutions of the plasma, suggesting that dilution favors dissociation of the plasmin-antiplasmin complex, though in normal plasma there is a sufficient excess of inhibitor to prevent activation.

It is an alteration of the plasmin-antiplasmin balance, therefore, that determines the presence or absence of fibrinolysis activity in the blood. Alterations resulting in an increased activity have been observed as follows:

- 1 Streptokinase increases the plasmin content of the plasma by activating available plasminogen, but does not appear greatly to affect the antiplasmin.

- 2 Chloroform destroys antiplasmin, thus releasing the plasmin normally in combination with it.

- 3 The spontaneous fibrinolytic activity observed in the authors' subjects is due to an increase in plasmin and also apparently to a decrease in antiplasmin.

The mechanism by which plasminogen is activated in these subjects is at present unknown.

STEPHEN A. ZIEGLER, M.D.

Levenson S. M., Green R. W., Taylor P. H. L., Robinson, P., and Others: Ascorbic Acid, Riboflavin, Thiamin and Nicotinic Acid in Relation to Severe Injury Hemorrhage, and Infection in the Human. *A. S. Surg.* 946, 124, 840.

Few careful studies other than those of ascorbic acid and vitamin K in relation to surgical conditions have been reported in the field of vitamin therapy. In the meantime all known vitamins are being used in the care of surgical patients, with increasing frequency and in increasing doses.

Recent work in the laboratory has shown that many vitamins play much more fundamental roles in the animal organism than that of merely preventing or curing the well known syndromes of scurvy, beriberi, pellagra, or hypoprothrombinemia. For instance, thiamin and nicotinic acid both play fundamental roles in the enzyme systems that control the metabolism of carbohydrates. Riboflavin is also important for the carbohydrate metabolism and, in addition, has a function associated with amino acid metabolism. Ascorbic acid is said to have a fundamental role in the formation of adrenocortical hormone. These functions indicate that these four vitamins play important roles in connection with recovery from shock injury and acute infections since disturbances in the metabolism of carbohydrate, protein, and of adrenocortical hormones are caused by these conditions.

The authors present data concerning 6 patients with severe injuries, hemorrhage, or infection who had marked abnormalities in the metabolism of ascorbic acid, thiamin, riboflavin and nicotinamide. They were cared for by the members of the "Burn Assignment" in a metabolic ward which was supplied with special nurses, a research dietitian, and facilities for accurate determinations of vitamins as developed

in the Harvard Fatigue Laboratory. Low concentration of ascorbic acid in the plasma, fasting or after saturation tests, and low excretions of all four vitamins under the same two conditions were found.

The study gives some further support to the idea that large doses of ascorbic acid, thiamin, riboflavin, and nicotinic acid may serve a useful purpose in the care of acutely ill people. HARRY W. FINE, M.D.

Slabe, F. W.: Fibromyositis, Including Its Industrial Implications and with Special Reference to Referred Pain. *Occup. Med.* 1946 320.

Fibromyositis includes conditions in which myositis (which is often an intramuscular fibrositis) and fibrositis, or both, predominate. It presents a localized or occasionally diffuse area of infiltration involving muscle or contiguous tissue. The observed pathological changes are inflammatory and minimal in the acute stage, but fibrotic and degenerative in the chronic stage. Firm, painful nodules, designated by the term "myogelosis," may occur in the affected muscle. The usual sites of involvement are the erector spinae muscles, extending from the neck to the pelvis, the glutei, and the muscles attaching to the shoulder girdle.

The mechanisms producing the symptoms of the disease are poorly understood, but many predisposing and associated factors are recognized. These include nutritional deficiencies, metabolic disturbances, foci of infection, fatigue, postural defects, exposure and constant repetition of given motions (as in the use of a screwdriver). The signs and symptoms may be difficult to elicit. In this respect a complete history is invaluable. Typically there is tenderness at the site of involvement with pain which is aggravated by use of the part, and often with referred pain which is greater than that felt in the primary site. Objectively the only finding may be an area of induration or muscle spasm. On occasion, a firm nodule may even be felt. In some cases, however, overlying muscles may obscure these findings. Isolation of the small area of tenderness which represents the primary site is so important as to justify a painstaking search. In making the diagnosis of fibromyositis, one is called upon to differentiate the condition from a strain of a ligament or muscle. The "pure" strain will give immediate pain experienced simultaneously with an incident or effort which is unusual and definite. It will produce some degree of immediate local incapacity and impairment of function. Under appropriate therapy its symptoms will subside. The "pure" instances of fibromyositis are those in which there is history of unusual effort for some time before the appearance of symptoms. There are mixed cases in which an acute strain may precipitate the symptoms of a fibromyositis, to which there has been a predisposition because of unusual heavy work, prolonged overuse of a part, or work in an unnatural position.

One of the most interesting features of this disease is the frequent occurrence of referred pain. This always arises from deeper structures, whether they be muscles, ligaments, fascia, or even peritoneum. It is diffuse and poorly localized pain which follows the dis-

MISCELLANEOUS

503

tribution of a spinal segment. There is usually tender-
ness of the area to which the pain is referred. Although
objective sensory changes may be absent, there fre-
quently is slight diminution or increase in sensibility to
light touch and pinprick. The patient may be able
only to describe the area as feeling different or
"tight." The referred pain originates in the primary
site of the disease but how this "trigger zone" initiates
it is not definitely known. Several interesting theories
are advanced. The author describes in detail the char-
acteristics of referred pain from the most frequent
sites of origin: the dorsolumbar region, the lower part
of the back, the shoulder girdle, and the lower part
of the back and the cervical region.

Treatment is prophylactic to some extent especially
in industry, where instruction in proper methods of
lifting, avoidance of prolonged repetition of motions,
and correction of working positions which are mechan-
ically unsound will eliminate certain predisposing fac-
tors. Specific therapy includes rest for the affected
part, the application of heat, the local use of counter-
irritants, deep massage, and the use of analgesics
particularly of the salicylates. The injection of a
local anesthetic into the trigger zone is a striking
therapeutic procedure and frequently has diagnostic
value.

The author recommends that the small isolated ten-
der zone be injected with from 5 to 20 c.c. of 1 per cent
procaine hydrochloride. He advocates injecting half
of the solution rather rapidly. If this increases the re-
ferred pain one may feel certain that the lesion is the
primary one. The remainder of the solution should be
injected slowly around the periphery of the area. The
treatment is effective in most cases but not all pa-
tients respond favorably. Some may experience severe
"after pain."

Coman, D. R.: Induction of Neoplasia In Vitro with
a Virus. Experiments with Rabbit Skin Grown
in Tissue Culture and Treated with Shope
Papilloma Virus. *Cancer Res.* 1946 6 605

Since neoplasia has been induced in tissue cultures
by a chemical carcinogen the question presented it-
self as to whether similar neoplastic transformation
of cells in vitro can be obtained by other types of
experiments such as viruses. The author designed
experiments to determine whether neoplasia can be
induced in tissue cultures of rabbit skin by papil-
loma virus.

The following criteria were adopted for the induc-
tion of neoplasia: (1) increased growth activity of
the epithelial cells in cultures after the introduction
of papilloma virus and (2) the formation of relatively
large tumors in the liver of the rabbit following the
implantation of such tissue cultures. Both criteria
were met by the author's experiments and he there-
fore concludes that papilloma virus is capable of
inducing neoplastic formations in vitro namely in
tissue cultures of rabbit skin.

Tumors resulted in the author's experiments only
when the skin treated with papilloma virus was im-
planted in the rabbit from which it had been re-

moved originally. This indicates that the skin had
not lost its individual specificity during tissue
culture.

The use of papilloma virus and rabbit skin in
vitro should serve as an excellent method for in-
vestigations of virus-cell relationships.

Burrows, H., and Hoch Ligeti, C.: Effect of Pro-
gesterone on the Development of Mammary
Cancer in C3H Mice. *Cancer Res.* 1946 6 603.

The effect of progesterone on the incidence of
spontaneous mammary tumors in the pure strain of
mice was investigated by the authors because it had
been previously found that the occurrence of mam-
mary cancer in RIII mice was considerably reduced
by progesterone, and because it has been repeatedly
suggested that in addition to the hereditary factors
in pure strain mice with a high incidence of mam-
mary cancer an excessive secretion of estrogen may
determine the incidence of these tumors.

Thirty mice of a high mammary cancer strain were
given subcutaneous injections of 1 mgm. of proges-
terone weekly. The authors were not able to establish
any differences in the frequency of the tumors and
the ages of these mice and of the 20 control animals
receiving injections of the solvent only.

The different results obtained by other writers in
similar experiments demonstrate the need for care in
attempting to generalize the results in different
strains of the same species. Obviously still greater
care is indicated in attempts to carry over the results
obtained in experimental animals to human pathol-
ogy.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Hartman, T. L.: Sulfonamide Sensitivity Deter-
minations of Hemolytic Streptococci Isolated
from Patients before and after Treatment with
Sulfadiazine. *Bull Johns Hopkins Hosp.* 1946
79 343

Recent epidemics of streptococcal infections caused
by sulfadiazine-resistant hemolytic streptococci fol-
lowing mass chemoprophylaxis programs have aroused
interest in this problem.

Nasopharyngeal cultures were taken from 40 pa-
tients on admission to the hospital and following sulfa-
diazine therapy. With 1 exception all of these 40 de-
veloped clinical evidence of scarlet fever. The bacteria
were typed by the precipitin method. Thirty-nine
cases presented group A hemolytic streptococci, those
of group C. Sulfadiazine was given as follows:
20 gm. initially, 10 gm. in 2 cases and 1 case presented
doses during the first day and 10 gm. for at least 4
for 5 doses during the succeeding days. Most patients
sprayed their nose and throat with a 5 per cent sulfa-
diazine in glycerine and saline solution, and gargled
with a 5 per cent sulfadiazine. The total amount of
sulfadiazine given varied from 14 to 75 gm. per pa-

cient, and resulted in blood levels from 2.0 to 12.0 mgm. per cent, with an average blood level of 7.3 mgm. per cent. After chemotherapy sulfadiazine sensitivity of the streptococci was tested by the method described by Wilson. No significant resistance against sulfadiazine was found in any instance.

Previously noted resistance to sulfadiazine by hemolytic streptococci is explained by the lower doses of sulfadiazine used for prophylaxis, and the longer period of administration. Resistance to drugs by bacteria is hypothesized as being due to mutation or adaptation to unfavorable environmental conditions.

C. FREDERICK KITTLE, M.D.

Lewis, L.: Therapeutic Trial of Penicillin in Tetanus. *Ann. Int. M.* 946 25 903.

Laboratory studies have indicated that penicillin is effective against the *Clostridium tetani*. Penicillin alone had not been critically evaluated in human tetanus infection. An opportunity for such observation in civilian casualties became available in the Okinawa campaign.

Patients with recently developed symptoms of severe tetanus, and who were not treated with or were unaffected by tetanus antitoxin were selected. Fifteen, of whom only 4 had received tetanus antitoxin were given penicillin; these 4 were included because they apparently had failed to benefit from the antitoxin. Nine patients had multiple shrapnel wounds, 4 gunshot wounds, 1 patient had undergone amputation of the right arm, and 1 had an undetermined injury; all of the patients had open, infected wounds. One patient received a local injection of penicillin but all the others received the drug by the intramuscular route. About 20,000 units of penicillin were given every 4 hours, except from 3:00 P.M. to 6:00 A.M. when no trained nurses were on duty. The daily dose was, therefore, 100,000 units, and the average duration of treatment was 5 days. Most patients received a total of 500,000 units or more, and 1 patient was given 1,500,000 units in injections around her wounds. Of this group of 15 patients, 7 recovered, 3 were benefited (including the patient who received the local injection) and 5 died.

There was no sharp alteration of the clinical course noted during the penicillin treatment, nor immediately following the injections, although in most instances the local wounds became cleaner. The course of the tetanus infection seemed no different from that in the controls, who received only prophylactic antitoxin and there was no evidence of a reduction of mortality in severe tetanus. There was no further improvement in cases which had failed to respond to antitoxin. In general recovery and improvement were gradual.

Four patients who had received antitoxin 3 of whom received large doses, showed a striking clinical improvement in contrast to the result obtained with penicillin.

Of 27 patients treated with small probably inadequate amounts of antitoxin, 16 recovered completely, 7 were benefited, and 3 died.

On the basis of this study the author concludes that there was no evidence of an effect of commercial penicillin against human tetanus infection. However the dosage might have been inadequate, and therefore large booster doses, similar to those used in subacute bacterial endocarditis, should be tried. Also different fractions of penicillin will have to be analyzed.

ARTHUR J. LEMER, M.D.

Hoffman, R. S., Dingwall J. A. and Andrus, W. DeW.: Studies on the Effects of Adult Animal Tissue Extracts on Wound Healing. *Ann. Surg.* 946 124 25.

The process of repair proceeds through an ordinary sequence in healing. The work here presented is based on the assumption that this healing cycle may be accelerated. The authors prepared an extract of sterile adult sheep hearts which had been finely minced in a blender with Tyrode's solution, cooled, and centrifuged, the extract being decanted and kept refrigerated.

The authors used 5 human volunteers between the ages of 30 and 50 years in good nutritional state. Under novocain anesthesia and completely sterile precautions, wounds were made in both anterior thighs. After 48 hours the larger of the defects was selected for treatment with the extract, while the smaller one was treated by constant dakinization. There was no evidence of infection in either wound in any of the subjects studied, and at regular intervals the circumference of these wounds was measured. Four of the 5 treated wounds were healed before the controls and 1 healed simultaneously with the control. In the wounds that were somewhat deeper it was observed that the extract had a marked stimulating effect on the growth of granulation tissue.

In the discussion it is concluded that the nutritional state, the hematologic picture, metabolic diseases, and infection all influence the rate of healing of wounds. More recently there have been other growth-promoting properties mentioned in the literature, some of which are chlorophyll, allantoin, and creatine. Many of these substances, however, have not been proved to be active on cells growing in vitro, nor do some of the clinical cases treated meet the requirements necessary to draw conclusions.

The authors believe that extract of adult animal tissue contains a substance that exerts a growth-promoting effect, and that this effect is the result of direct action on the metabolic mechanism of cellular proliferation. It is not thermostable and it is nondialyzable; its activity does not vary greatly with the change in pH, nor does it change appreciably over a wide range of concentration. It is thought that the active factor is most probably a protein, not necessarily a nucleoprotein, but rather an enzyme which plays a part in nucleoprotein formation. Exposure to ultraviolet light, and mixing with sulfadiazine or penicillin did not alter the growth-producing properties.

The article also includes a brief resumé of the method of preparation of the extract.

DUCTLESS GLANDS

Cesarelli A. The Surgical Treatment of Myasthenia Gravis (Tratamiento quirúrgico de la miastenia gravis) *Bol Soc cir Rosario* 1946 13 306

The author has observed that extirpation of the thymus gland has shown the existence in certain cases of a relationship between this gland and the symptoms of myasthenia gravis. Thymectomy is indicated in patients with myasthenia gravis when a tumor of the thymus is demonstrated for in these cases the best results were obtained. Pneumomediastinal x-rays were of great diagnostic value in the visualization of small tumors of the thymus. In special cases with lack of demonstrable tumors and in which medical treatment fails it is justifiable to operate although in the acute crisis of myasthenia gravis surgery is contraindicated and the administration of prostigmine is necessary. In 1 of 2 patients who tolerated the operation it was possible to observe a definite improvement in the condition and in the other the symptoms disappeared with apparent cure after a period of 9 months.

ARTHUR F. CIPOLLA, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Isaacson, N. H., and Rapoport P. Eosinophilia in Malignant Tumors: Its Significance. *Ann Int M.* 1946 25 893

The authors report 34 cases of pronounced eosinophilia associated with malignant tumors. Nineteen of these were reviewed from the literature and 15 were observed among 2,363 cases of malignant tumors at the Jewish Hospital of Brooklyn during the past 8 years. Six per cent of the total white count is considered the upper normal for eosinophilic leucocytes. In the 19 case reports of eosinophilia with malignancy the eosinophil counts varied from 10 to 70 per cent. In the authors' 15 cases, the range was from 10 to 32 per cent but in most of the cases it was between 15 and 25 per cent.

In 90 per cent of all cases, metastases were present. In 7 they were suspected but not proved and in 1 case they were neither demonstrable nor suspected. The authors believe, however, that eosinophilia is indicative of dissemination of the malignant process when it is associated with a malignant tumor and other causes are ruled out.

The following causes of eosinophilia in malignant tumors have been suggested: (1) necrosis of tumor tissue with eosinophilic response; (2) bone marrow metastases with stimulation of eosinophilic production at these sites; (3) the pressure of metastases on the vagus with vagal reflex; (4) the connective tissue surrounding the tumor; and (5) a familial eosinophilic predisposition with the response to foreign protein of the tumor cells as a provocative agent. There is no satisfactory theory of pathogenesis and no definite cause for eosinophilia in malignant tumors has yet been established according to the authors.

EXPERIMENTAL SURGERY

McCarthy M. D., Parkins, W. M., and Zerbe J. W.: Comparative Efficacy of Blood from Normal and from Burned Donors in Experimental Burns. *Arch Surg.* 1946, 53 570.

The experiments reported by the authors lend credence to the popular hypothesis that severe burns produce a circulating toxin. Previous experiments had demonstrated that a single transfusion of blood from burned rats was not lethal to a normal rat in amounts up to 2 per cent of its body weight. Therefore, it was decided to increase the potential sensitivity of the recipient animal to the hypothetical toxin contained in the donor blood by subjecting the recipient to a standardized burn before the transfusion.

Forty-eight rats were subjected to a standardized scalding burn of the back. Sixteen of these were not treated in any way. Sixteen were given an infusion of normal blood equivalent to 2 per cent of their body weight. Sixteen were given an equivalent infusion of blood withdrawn from burned rats. The donors had been subjected to a burn of 45 per cent of their body surfaces, which in every case proved fatal within 24 hours. Ten days after being burned the rats treated with normal blood had a survival rate of 100 per cent, and both the untreated group and that given post burn blood had a survival rate of 56 per cent. Hematocrit data obtained from the three groups did not indicate that increased mortality was a direct result of increased hemococoncentration.

To determine the culpable fraction of 'postburn' blood it was centrifuged and its cells suspended in normal saline solution. When this suspension was infused into burned animals, the survival rate (66%) was not significantly different from that of burned animals infused with suspensions of normal cells in saline solution (83%). This appeared to indicate that the cause of the ineffectiveness of whole post burn blood lay in the plasma. The plasma potassium level of 'postburn' blood was slightly higher than that of normal blood (33.1 mgm./100 c.c. as against 30.5 mgm.) but this difference was not significant. However there was a significant difference in hemoglobinemia. This was 407 mgm./100 c.c. for postburn plasma as compared to 75.0 mgm. for normal plasma.

The authors emphasize that blood from severely burned rats was completely ineffective when transfused into rats subjected to a standardized burn sufficiently severe to give a 44 per cent mortality in the untreated controls. The fact that other rats subjected to the same burn but transfused with normal blood had a 0 per cent mortality is statistically significant.

Jenkins, H. P., and Janda, R.: Studies on the Use of Gelatin Sponge or Foam as a Hemostatic Agent in Experimental Liver Resections and Injuries to Large Veins. *Ann Surg* 1946 123 952

In a series of 12 dogs operated on with aseptic technique and under ether anesthesia a considerable

portion of a lobe of the liver was resected by simply cutting it off with scissors. The gelatin sponge was prepared for use by moistening it in physiological saline solution expressing the air and removing the excess saline solution by compressing it between dry gauze. The large gelatin sponge was then placed over the freely bleeding stump of liver so that it overlapped the upper and lower surface of the liver. It was held in place with firm pressure for from 5 to 10 minutes. Good apposition of the sponge to the bleeding surface is necessary as this produces a relatively rapid adhesive effect between the raw surface of the liver and the sponge. In all of the animals, hemostasis was obtained by the application of the gelatin sponge alone without supplementary suturing. In several instances it was necessary to reapply a fresh gelatin sponge in order to obtain complete hemostasis.

In a series of 36 dogs, operated on in a similar manner the femoral, jugular or renal vein or the vena cava was exposed. A stab incision was made with a scalpel or a portion of the wall of the vein was excised. The gelatin sponge was applied immediately to the bleeding vein and pressed firmly in place over the wound for a minute or two. It was found that pressure with the gloved finger directly on the sponge on the vein was satisfactory. The bleeding was completely controlled by this method in all the experiments but 2. In 1 case secondary hemorrhage occurred from the superior vena cava apparently because of dislodgment of the sponge after the chest wound was closed.

Gelatin sponge was also used on 76 patients in whom troublesome bleeding could not be completely controlled by other means. The extent of the bleeding in these clinical cases cannot be compared with

that obtained in the experimental animals, so that the value of gelatin sponge as a clinical hemostatic has yet to be demonstrated.

A substantial part of the hemostatic action of gelatin sponge may be due to the spongy material itself. It is possible that the enormous surface area of the myriads of interstices may attract and damage the platelets and thus liberate thromboplastin. This, in combination with the calcium and prothrombin in the blood may elaborate enough thrombin to initiate the clotting mechanism. In the clinical use of gelatin sponge it is recommended that thrombin be used to obtain the maximum hemostatic effect.

Although the absorption time of the sponge used may be more than adequate under favorable conditions the sponge may be rapidly liquefied in the presence of a large concentration of leucocytes. A somewhat tougher and stronger spongy material than is now available seems to be desirable. This would make it possible to suture the sponge in place by some sort of basting stitch.

The excellent protective cover which the sponge appears to offer to the healing process across the stump of the liver at the line of resection is of considerable interest as is also the structural support it seems to give to the reparative process.

The possibility that a propagating thrombus may arise from the sponge plugging a rent in a vein must be considered in the clinical application of this experimental work. Heparin and dicoumarol therapy may be required to prevent this.

The particular promise which such hemostatic substances offer is that they may make possible more extensive surgery with greater safety especially in the treatment of carcinoma than has been feasible in the past.

THE COMBINED THORACICOABDOMINAL APPROACH WITH PARTICULAR REFERENCE TO ITS EMPLOYMENT IN SPLENECTOMY

B NOLAND CARTER, MD Cincinnati Ohio

WHEN one reviews the literature dealing with splenectomy performed for an enlarged spleen and reflects on his own experiences in such operations it becomes evident that the technical difficulties encountered are chiefly those resulting from lack of completely adequate exposure. Various types of incisions have been advocated for splenectomy all aimed at providing an easier and freer access to the operative field. Among these are the T incision with one arm placed through the left rectus muscle and the other extending through the muscles of the abdominal wall toward the flank; the subcostal incision placed just below and parallel to the costal margin; and the transverse incision beginning at the midline half way between the xiphoid and umbilicus and extending through the abdominal wall laterally to just above the crest of the ilium. In the case of a grossly enlarged spleen none of these incisions is adequate because they do not allow access to those portions of the operative field in which lie the most potent sources of danger and difficulty. These areas are the upper pole of the spleen, its diaphragmatic surface and its posterior aspect. At these points are found the dense adhesions, the dilated thin walled collateral vessels, and

some of the normal splenic ligaments. Until these structures are divided the spleen cannot be mobilized sufficiently to permit easy and safe management of the pedicle. It is however in attempts at blind mobilization of the large spleen that inaccessible vessels are torn and nearby structures damaged. In an attempt to meet this situation Singleton has advised the opening of the lesser peritoneal sac and ligation of the splenic vessels as they course along the upper surface of the pancreas as a first step in the procedure and having thus controlled the main blood supply to the spleen to proceed with its mobilization and removal.

When a large spleen is encountered its very size in comparison with the length of the abdominal incision which can be made over it is a potent factor militating against easy exposure. The spleen is so large that it fills the incision of its own accord, thus making easy access to remote portions of the operative field practically impossible. This is particularly true where there is a narrow costal angle with a rib cage covering the greater part of the upper left quadrant. Actually the enlarged spleen lies mostly beneath the ribs in contact with the diaphragm (Fig. 1) placing the surgeon at a distinct disadvantage when working through an abdominal incision.

Since 1939 it has been our practice to perform esophagogastrostomies through a trans-thoracic approach with division of the dia-

From the Department of Surgery of the College of Medicine, University of Cincinnati and the Cincinnati General Hospital, Cincinnati, Ohio.

phragm and it has become increasingly evident to us that such an approach offers an unusually good exposure of the spleen. Consequently this type of approach was recently utilized in this clinic for the removal of a spleen of normal size which had been ruptured for several days before admission of patient to hospital and which was surrounded by a fibrous blood clot. In this instance the costal arch was extremely narrow and the diaphragm quite high so that it was considered simpler to approach the spleen through the chest. The thorax was opened by an incision placed in the seventh interspace, and the ribs were spread widely the diaphragm was opened and the spleen lying in clear view could be easily freed from its many adhesions and the pedicle brought into the operative field. The simplicity of this procedure immediately suggested the possibility of attacking an enlarged spleen by a transthoracic approach. It was felt however that when the spleen was grossly enlarged the incision through the diaphragm might not be adequate to permit easy delivery of the enlarged organ and that one would be handicapped in much the same way as he would be if he were using an abdominal incision. Therefore it seemed logical to utilize a combined abdominal and thoracic incision the thoracic portion of which would give a direct approach to those aspects of the spleen inadequately exposed by an abdominal incision while the abdominal portion would permit wide access to the lower portion of the spleen and also permit the thoracic cage to be spread more widely. The over all length of the combined incision would allow for easy delivery of the enlarged spleen.

The opportunity to utilize this proposed incision first presented itself in June 1946 in the case of a 37 year old white man with Banti's syndrome. On June 6 1945 he had been admitted to the Cincinnati General Hospital with a perforated duodenal ulcer for which he was operated upon with a simple closure of the ulcer. His convalescence was a stormy one complicated by a right subphrenic abscess and a right empyema. During this admission to the hospital he showed a slight degree of icterus with some ascites. Under bed rest and digitalis these manifestations

rapidly disappeared. At the time of jaundice and ascites the laboratory findings were as follows: cephalin flocculation test 2½+ in 24 hours and 3+ in 48 hours bromsulphalein retention 65 per cent in 30 minutes and 100 per cent in 5 minutes blood phosphatase 5.9 hippuric acid excretion test 175 grams galactose tolerance test 3.5 grams excreted.

His second admission was on September 12 1945. The spleen was enlarged at this time being three fingerbreadths below the costal margin and had apparently been the site of an infarct causing pain in the upper left quadrant and tenderness over spleen. A diagnosis of probable Banti's disease was made and he was referred to the out-patient clinic. During the next 6 months he had repeated splenic infarcts and the previously noted enlargement of the spleen continued but there was no ascites.

He was admitted to the surgical service in the Cincinnati General Hospital on June 17 1946 complaining of weakness, jaundice and dull aching pain in the left upper quadrant. He showed evidence of considerable loss of weight and appeared chronically ill. There was a slight icterus present not accompanied by itching. The liver could not be felt. The spleen was grossly enlarged, with its lower pole 2 inches below the level of the umbilicus and was very firm. There was no ascites. The laboratory findings were as follows: cephalin flocculation test 3+ in 24 hours and 3+ in 48 hours prothrombin time 12 seconds (12 to 13 seconds normal) bromsulphalein test showed 100 per cent in 5, 30 and 45 minutes blood urea nitrogen 14 milligrams per cent Kahn negative icteric index 7. X-ray studies revealed varices scattered throughout lower half of esophagus. After suitable replacement therapy patient was operated upon June 20 1946.

The operative technique employed was as follows. Under intratracheal gas oxygen and ether anesthesia a transverse incision was made from a point midway between the xiphoid and the umbilicus to the costal margin at the site of the eighth costal cartilage and prolonged in the eighth interspace to the mid-axillary line (Fig. 2 insert). The rectus and oblique muscles were divided in line with the skin incision down to the peritoneum and the muscles on the chest wall were incised down to

the pleura (Fig 2) The peritoneum was now opened as far as the costal cartilage which was cut across and the pleura opened throughout the length of the thoracic portion of the wound Both the abdomen and the thorax having been thus entered, the diaphragm was incised from its attachment at the costal margin to the posterior angle of the thoracic incision (Fig 3) A rib spreader was inserted and a remarkably wide exposure of the greatly enlarged spleen resulted Actually one could see the organ from its superior to its inferior poles (Fig 4) The diaphragmatic surface could be visualized completely as well as the entire greater curvature of the stomach Many dense and vascular adhesions could be seen extending from the spleen to the diaphragm at the upper pole and on the posterior lateral surface of the spleen The splenic flexure of the colon was in plain view and the left kidney could be made out readily The splenocolic and splenorenal ligaments were ligated and divided (Fig 5) The vascular adhesions mentioned were ligated and divided with great ease since they were completely in the operative field and under direct vision The gastrosplenic ligament was like

Fig 1 The position of the enlarged spleen beneath the rib cage, necessitating blind dissection in order to mobilize it for delivery through the abdominal incision

Fig 2 The incision has been made in the line shown in the insert, and has been deepened through the muscles down to the pleura and peritoneum The 8th costal cartilage has not been divided.

Fig. 3. The peritoneum has been opened, the costal cartilage divided, and the pleural cavity entered. The diaphragm is now being divided, thus throwing the peritoneal and pleural cavities into one.

Fig. 4. The extent of the exposure obtained in the case of grossly enlarged and adherent spleen. Note the free access obtained to the diaphragmatic surface of the spleen with its many vascular adhesions.

wise ligated in segments and divided without difficulty (Fig. 6). The spleen was then delivered readily through the long widely spread incision and turned toward the right (Fig. 7). The tail of the pancreas was visualized and

the splenic pedicle freed from it. With the left hand beneath the spleen and its pedicle the latter was readily isolated into its artery and veins (Fig. 8). The artery was doubly ligated and divided and the spleen removed. There

Fig. 5 The splenocolic and splenorenal ligaments have been divided. The vascular adhesions between the spleen and the undersurface of the diaphragm are being ligated prior to division.

Fig. 6 The exposure of the gastrosplenic ligament, showing the ease with which the ligament can be isolated into segments and divided. The splenic vessels are likewise shown.

was virtually no loss of blood since all structures could be visualized before ligation and division. It was never necessary to perform blind dissection in an inaccessible re-

Fig. 7 The spleen having been mobilized is turned to the right and freed from the tail of the pancreas.

Fig. 8 Exposure of the pedicle. The arteries have been ligated and divided. A vein is being ligated.

gion the entire procedure was done with great ease.

The diaphragm was sutured with interrupted figure-of-eight sutures of silk (Fig 9A) the chest wall was closed by means of one peri-

costal suture of braided silk and a continuous suture of silk in the overlying muscles (Fig 9B). Two sutures of silk were placed in the perichondrium of the divided cartilage and gave a snug approximation of this structure.

Fig. 9. A The diaphragm is being closed with figure-of-eight sutures. B One pericostal suture of braided silk has been tied and has approximated the ribs. The muscles of the chest wall are being closed with a continuous silk suture. C, The chest wall closure has been completed. The peritoneum has been closed with a continuous suture of silk and the sheath of the rectus muscle is being sutured with figure-of-eight stitches of silk.

The peritoneum was sutured with continuous silk and the sheaths of the divided abdominal muscles were closed with interrupted figure-of-eight sutures of silk (Fig. 9C). The skin was sutured with interrupted silk. No drainage of the pleural cavity or wound was instituted. The operation was well tolerated and at no time did the pulse go above 80. The blood pressure was 140/85 at start of the operation and 102/80 at end of procedure.

The convalescence was uneventful. The patient was singularly free from pain after operation and was ambulatory on the second postoperative day. The wound healed by first intention and 7 months after operation there was no evidence of postoperative hernia.

After this rewarding experience with the incision described it was decided that considerable advantages were afforded which would make it applicable to operations for other surgical conditions encountered in the left upper quadrant of the abdomen. It was next employed in the removal of a leiomyoma situated adjacent to the esophagus on the antero-

lateral aspect of the stomach. Again the access to the lesion was strikingly easy and the tumor was resected without the difficult vigorous and often futile attempts at retraction of the costal margin and the assumption of awkward positions by the surgeon. It has been utilized also in the resection of the cardiac portion of the stomach for carcinoma, and in removal of lesions of the lower end of the esophagus followed by esophagogastrostomy.

HISTORICAL REVIEW

In an effort to determine the experiences of others in the use of this approach which we had never seen utilized nor recalled having seen reported the literature was surveyed and was found sufficiently interesting to warrant a short historical review. The history of the combined thoracoabdominal approach dates back to the last decade of the nineteenth century and the efforts of Lannelongue and Michel to gain a wider exposure for operations on the cardiac portion of the stomach. Von Mikulicz as reported by Gottstein per-

Fig. 7. The spleen having been mobilized is turned to the right and freed from the tail of the pancreas.

Fig. 8. Exposure of the pedicle. The arteries have been ligated and divided. A spleen is being ligated.

gon the entire procedure was done with great ease.

The diaphragm was sutured with interrupted figure-of-eight sutures of silk (Fig. 9A) the chest wall was closed by means of one pen-

costal suture of braided silk and a continuous suture of silk in the overlying muscles (Fig. 9B). Two sutures of silk were placed in the perichondrium of the divided cartilage and gave a snug approximation of this structure.

Fig. 10. Types of combined thoracic and abdominal incisions with authors and dates.

field for tumor of the cardia was obtained. The importance of abdominal exploration prior to opening of the chest was stressed.

In 1946 Humphreys reported 12 operations using the combined incision for carcinoma involving both the esophagus and the cardia with a 50 per cent mortality. He opened the abdomen through an oblique incision from the costal margin at the level of the eighth interspace to a point just right of the midline about 2 centimeters above the umbilicus. After determination of operability this in-

cision was extended directly upward into the chest over the eighth interspace to the posterior axillary line (Fig. 10E). The diaphragm was divided from its origin at the costal margin between the eighth and ninth ribs as far as the esophageal hiatus. The esophagus was freed upward as far as necessary and the stomach freed toward the pylorus also as far as was necessary. Of the 6 patients surviving the operation 3 died of metastases and 3 were alive at the time of the report 5, 6 and 15 months after operation respectively. Five

formed the first operation leading to this approach to be done on a living patient in 1896. His procedure however was specifically designed to avoid damage to the pleura. After making an incision from the xiphoid to the umbilicus, then perpendicularly to the left and then perpendicularly upwards he resected the ribs and carefully laid back the pleura before extirpating a carcinoma of the lower esophagus and cardia. He modified the incision somewhat at a later operation (1899) so that after the initial midline incision the second started perpendicularly and then shifted to go obliquely upwards and out but he again retained the integrity of the pleura. Both patients died shortly after operation.

Marwedel recorded the next such attempt in 1903. After intensive study on the cadaver he successfully performed an operation for stenosis of the esophagus using an incision which followed the costal arch. He also avoided entering the pleura, and devised a complicated maneuver for securing wide exposure without entering that cavity.

In 1909 Tiegel (16, 17) reported a case of Henle in which a thoracoabdominal approach was carried out in two stages. Laparotomy was performed first, operability determined and the upper part of the stomach mobilized and incised below the tumor. A Murphy button was placed in the distal opening and the upper part closed by suture. After closure of the abdominal wound a left thoracotomy was performed and the esophagus severed above the tumor. An esophagogastrostomy was then completed with the button. The patient died shortly after operation of collapse of the left lung.

Wendel performed a similar operation in 1909 however he performed thoracotomy first opening the pleura under pressure. A tumor was found on the posterior wall of the esophagus, partly above and partly below the diaphragm. Laparotomy was done after closure of the thoracic wound and tumor resected through abdomen. This patient also died shortly after operation autopsy a bloody effusion in the left pleural cavity.

In 1910 Janeway and Green carried out a two stage procedure performing laparotomy first followed by thoracotomy. Their patient

died 54 hours after operation of empyema. At that time in reporting the case they made the recommendation that in the future the operation should be performed through one incision rather than two suggesting the incision actually used by Ohsawa 23 years later.

Ohsawa (1933) was the first to report a combined incision with 8 survivals in 18 operations for tumors of the lower esophagus and cardia. He made a midline or a left pararectal incision from the seventh costal cartilage to just above the umbilicus and after opening the peritoneum to inspect the viscera continued this incision upward and laterally along the chest wall to the inferior angle of the scapula (Fig. 10A). After resecting segments of the seventh and eighth ribs he incised the pleura in the seventh intercostal space. The costal arch in the seventh interspace was cut through and the diaphragm divided to the esophageal hiatus thus converting the abdominal and thoracic cavities into a single operative field.

This operation did not meet with immediate approval but rather was felt to be one of too great magnitude. In condemning the procedures of both Marwedel and Ohsawa Garlock (4, 5) suggested exploration through a small upper left rectus incision for determination of operability. After closure of this wound he preferred to operate through the thorax.

Loucks and Wu reported 6 successful resections of carcinoma of the esophagus via the thoracoabdominal approach in 1942. They began the incision in the lower part of the interscapular region and continued downward and anteriorly along the seventh rib, extending into the hypochondrium to the lateral border of the left rectus muscle (Fig. 10C). After resecting the entire length of the seventh rib they entered the pleura and divided the costal margin through the cartilage. With the peritoneal cavity exposed at lower end of the incision a single operative field was made of pleural cavity and upper abdomen.

Brock (1942) made a midline supraumbilical incision with a second obliquely upwards along the sixth intercostal space from the middle of the first (Fig. 10B). After dividing the costal margin and separating the diaphragm from the costal attachment, the operative

REOPERATIVE SURGERY FOR RECURRENT PEPTIC ULCERATIONS

M E. STEINBERG M D *Portland Oregon*

THIS report is based on 73 subtotal gastrectomies in 71 patients whose previous gastric operations proved unsuccessful

Five patients have had their first operation by myself. Three of these 5 original operations were subtotal gastrectomies with Finsterer's exclusion operation in which the antral mucosa was left intact. These patients developed jejunal ulcers and were operated on again by me. The fourth patient had a Billroth I resection for a gastric ulcer. She developed symptoms because of severe adhesions. The Billroth I operation was dismantled and turned into a typical retrocolic Hofmeister Finsterer procedure. In the fifth patient a perforated duodenal ulcer was excised and a Judd pyloroplasty performed. The patient underwent a resection later because of the recurrences of the duodenal ulcer. Of the 66 patients with gastrectomies who had had their original operations elsewhere, 2 were operated upon by me several times subsequent to their first operations elsewhere.

The 71 gastrectomized patients had had 107 gastric operations of various types previous to the final gastrectomy.

Epigastric pain, particularly shifting to the left, following a gastrectomy frequently denotes a jejunal ulcer. Hemorrhage or pain in a patient who has had any type of a Billroth II gastrectomy suggests a jejunal ulcer or jejunitis. The symptomatology of recurrent and jejunal ulceration is not necessarily characterized by the pain and food relief syndrome. X-ray and gastroscopic examination and even abdominal exploration often fail to give positive evidence of the presence of a frank jejunal ulcer unless the gastrojejunal anastomosis is dismantled during the exploration.

Epigastric pain, nausea and vomiting may also be caused by motor disturbances from severe adhesions or a faulty technique.

A brief analysis (Tables I and II) is also made of 300 personally performed primary gastrectomies for benign gastroduodenal ulcerations.

TABLE I — ANTECEDENT GASTRIC
PROCEDURES IN 71 PATIENTS

No. of patients	71
No. of previous gastric operations	107
Total No. of gastric operations	178
No. of personally performed secondary radical gastrectomies	73
No. of patients originally operated upon elsewhere	66
No. of patients originally operated upon by me	5

TABLE II — TYPE OF ANTECEDENT GASTRIC
PROCEDURES WHICH RESULTED IN FAILURE

	No. Cases
Gastroenterostomy with enteroanastomosis	1
Gastroenterostomy (retrocolic)	30
Von Eschberg exclusion operation with gastroenterostomy	4
Finsterer's original exclusion operation (mucosa not ablated) with radical gastrectomy	6
Finsterer's original exclusion operation (mucosa not ablated) with a minimal resection	1
Finsterer's original exclusion operation (mucosa not ablated) with radical gastrectomy and enteroanastomosis	1
Dismantling of gastroenterostomy	1
Conservative retrocolic gastrectomy	1
Billroth I gastrectomy	1
Duodenojejunosomy	1
Excision of duodenal diverticulum	
Excision of gastric ulcer	6
Excision of chronic and perforated duodenal ulcers and various pyloroplastic procedures	36
Miscellaneous and undetermined procedures, such as gastrotomy, closure of perforation with pyloroplasty, exploration and postoperative obstruction	11
Jejunostomy	1
Closure of perforated jejunal ulcer	7
Radical retrocolic gastrectomy	0

THE ETIOLOGY AND PREVENTION OF POSTOPERATIVE JEJUNAL ULCERS

Postoperative jejunal ulcers take place after a gastroenterostomy and also following a Billroth II gastrectomy. Only a few primary jejunal ulcers have been reported. It is evident

From the Physiology Department, University of Oregon Medical School and the Emanuel Hospital, Portland, Oregon.

combined incision procedures were carried out for carcinoma involving the cardia only with no operative mortality. Two of these operations were carried out entirely through the abdomen and in the other 3 the thoracic esophagus was not disturbed. Two of these patients were living at the time of the report 2 and 2½ years after operation respectively.

The most recent report of the thoracic-abdominal approach is that of Garlock (6) (1946). His procedure adopted after discussion with Humphreys began with a 3 inch incision along the outer edge of the rectus muscle. After completion of the abdominal exploration the first incision was extended over to and along the line of the eighth inter space (Fig 10D). The intercostal muscles and pleura were divided and the diaphragm cut across as far as the esophageal hiatus. This procedure produced a wound which could be opened as widely as necessary by a rib-spreader

COMMENTS

There are several distinct advantages in the use of the combined thoracoabdominal incision. The chief one of these is that it affords a wide and ready access to portions of the abdomen not obtainable when abdominal or thoracic approaches alone were utilized. Unless one has actually used or seen the operative procedure it is difficult to realize the ease with which operations can be performed on organs situated high in the upper quadrants of the abdomen. We have not used it on the right side but it should be extremely useful in an attack on certain lesions of the right lobe of the liver. The performance of the abdominal portion of the incision first permits exploration to determine operability after which the thoracic incision may be added if indicated.

Though the operative approach appears to be one of considerable magnitude and is more time-consuming both in its performance and in its closure. In our experience it is as well tolerated under intratracheal positive pressure anesthesia, as are extensive abdominal incisions. The ease of access afforded with consequent more rapid performance of operative procedures compensates for the additional time required to make and to close the in-

cision. The patients on whom this combined incision has been used have been remarkably comfortable after operation and certainly have not had more pain than those with large abdominal incisions. The intercostal incision without rib resection has been adequate in the way of exposure though there is no good reason why a rib should not be resected or why short segments of the ribs bordering the incision should not be removed if additional exposure is needed. None of our patients has shown instability of the chest wall after division of the eighth costal cartilage which is quite small at its point of division and which can be well approximated by sutures in the perichondrium after the pericostal suture has been tied. No postoperative hernias have been observed though the longest time since operation has been only 8 months.

CONCLUSIONS

- 1 The combined thoracoabdominal approach described has been well tolerated under intratracheal anesthesia with positive pressure.
- 2 A remarkably good exposure is afforded which permits easy surgical attack on lesions high in the upper quadrants of the abdomen.
- 3 The postoperative course of the patients thus operated upon has been striking in lack of pain or discomfort and no postoperative hernias have occurred although the follow up period has been only a few months.

Fig 1 No B-37555 E. H. About three fourths of the remaining gastric tissue was removed following a previous gastrectomy for a duodenal ulcer. An acutely perforated jejunal ulcer took place within 1 year following the original gastrectomy which was presumed to have been radical.

Fig 2 No B-64170-E. H. About three fourths of the remaining gastric tissue including a jejunal segment was removed following a previous gastrectomy for a duodenal ulcer. Jejunal ulcerations with repeated hemorrhages took place within 1 year following the first gastrectomy which was presumed to have been radical.

of the stomach. It has been suggested that it is not necessary to resect three fourths or four fifths of the stomach tissue since a certain percentage of jejunal ulcerations will take place irrespective of the amount of stomach resected. There is more than slender evidence to refute this assertion. It has already been mentioned that animals cannot be uniformly protected against jejunal ulcers by minimal resections (18). It was conclusively demonstrated that a subtotal resection of the stomach with a wide stoma performed according to the Billroth II method (Finsterer Hofmeister) has never been followed by a peptic ulcer in our experiments even in the presence of an artificial link in the jejunum. This we consider of scientific and clinical interest and importance. On the other hand the Billroth I anastomosis end-to-end and the minimal resection of the stomach according to the Billroth II method have given rise to jejunal ulcers (18). Lorenz and Schur pioneers in gastric resection have reported that the reduction in acidity after gastrectomy parallels the amount of gastric tissue removed. Jejunal ulcerations were not infrequent following minimal resections. Some surgeons of experience have abandoned the retrocolic type of resection because of postoperative difficulties or because of possible injury to the middle colic artery if reoperation should become necessary for a jejunal ulcer. Although the antecolic anastomosis is easier to perform and is less time-consuming it is my opinion that the frequency of jejunal ulcerations following the

antecolic minimal resection will either approximate or exceed the frequency of jejunal ulcerations following the posterior gastroenterostomy. In a series of 260 consecutive antecolic conservative gastrectomies Rienhoff reports 83 cases or 32 per cent of patients who developed such complications as pain, hemorrhage or jejunal ulcers. Pain or hemorrhage which follows a gastrectomy most frequently denotes jejunal ulcer or jejunitis. Kiefer reports 6.9 per cent jejunal ulcers and 4.6 per cent hemorrhage in 173 patients who have undergone extensive gastric resections for duodenal ulcer. The percentage of the proved and presumed jejunal ulcers is not as high as in the Rienhoff report because of the more radical type of the resections in the Lahey technique. The 11.5 per cent of unsatisfactory results however is high in comparison to the subtotal standard retrocolic resection. The discrepancy between the results in the subtotal retrocolic resection and the results in the Lahey subtotal antecolic resection is in all probability due to the long proximal jejunal loop which is a predisposing factor to jejunal ulcerations (9). Rienhoff and Kiefer's reports are of significance since the technique of gastrectomy in both instances has been described in detail.

then that it is the new environment at the jejunal segment following the gastrojejunal anastomosis which is responsible for the jejunal ulcerations. Exalto, Mann and Williamson, Ivy and Dragstedt, Steinberg and Proffitt as well as numerous other investigators have succeeded in producing jejunal ulcers with regularity by diverting the alkaline duodenal contents away from a newly created gastrojejunal anastomosis. Though the efforts of these numerous investigators have been important, the surgeons preceded the experimental workers by unwittingly performing operations on patients which were similar to the experimental methods of Exalto and others. The gastroenterostomy, the Y anastomosis of Roux, the enteroanastomosis and the Von Eiselsberg exclusion operation were frequently followed by jejunal ulcerations. Such postoperative ulcerations are more significant than the ulcers produced by the various experiments. Under parallel conditions of research, animal experimentation cannot hope to compete with the importance of careful investigations carried out on patients. The short-circuiting operations of Exalto are mutilating in the manifest physiological changes which they produce (18). In order to mitigate the mutilating short-circuiting operations of Exalto and also of Mann and Williamson, I have sidetracked the alkaline duodenal contents 60 centimeters or less from the pylorus in all the animal experiments previously reported. The introduction of hutmine beeswax by Code and Varco for the production of experimental ulcers has now replaced all the unphysiological short-circuiting operations. The grave nutritional and metabolic disturbances which are brought about by animal experiments do not follow the usual surgical procedures used in the treatment of peptic ulcerations.

It becomes apparent that the failures after gastric operations are more important than the animal experiments when it comes to evaluating the conditions under which postoperative ulcers develop. Statistics reporting jejunal ulcerations are of no value unless careful and detailed descriptions of the operative procedures are given. In reporting the disappointments and failures following gastrectomy it is

not a matter of indifference simply to group the resections into Billroth I or Billroth II. From the experimental evidence and from clinical experience certain modifications of the Billroth II procedures are destined to result in a great many more failures than the standard subtotal retrocolic gastric resection popularized by Finsterer. It is quite obvious that if minimal resections, subtotal retrocolic resections or antecolic resections and also exclusion operations or resections combined with the Y anastomosis or enteroanastomosis are all placed in one group, the percentage of failures will be credited to the gastrectomy irrespective of the method used. It is also my impression that the original Billroth II procedure which creates a blind terminal sac will compare unfavorably with the typical Hofmeister-Finsterer method in spite of a radical resection.

The analysis of the failures after gastric operations parallels the lessons learned from the experimental laboratory. Using the modified Exalto short-circuiting operation I was able to demonstrate in a large series of experimental animals that only a subtotal resection is able to protect the animal against jejunal ulcerations. However, if the gastrojejunal stoma is very small, a jejunal ulcer will take place in spite of a major resection. Some few years ago, while visiting a gastroenterologist, a patient was presented who had had repeated stomach resections and who still harbored a jejunal ulcer in spite of the fact that only a very small part of the stomach was left. The gastroenterologist was at a loss not only as to the prognosis but also as to the cause of this tragic condition. It was suggested that a Murphy button anastomosis which would result in a very small stoma could well have explained the repeated jejunal ulcerations. The surgical record actually showed a Murphy button had been used in the gastrojejunal anastomosis. Kinks and narrowing of the lumen of the jejunum distal to the gastrojejunal anastomosis should also be avoided. A kink distal to the jejunal anastomosis may produce a stasis in the jejunum and create a favorable condition for the development of a jejunal ulcer (18).

Again it is not a matter of indifference whether one removes a smaller or a larger part

Fig. 3. g, This represents the typical and original distal "Y" anastomosis of Roux. It is most likely to result in a recurrent jejunal ulcer. h, This represents a type of exclusion operation recommended by Von Eiselsberg and Devine. The proximal gastric segment is closed at its distal extremity creating a pouch. This type of an operation will rarely escape a jejunal ulcer. i, This is another type of the Von Eiselsberg or the Devine procedure. A jejunal ulcer is also most likely to take place following this procedure. j, A long loop antecolic anastomosis is a predisposing factor to jejunal ulcerations. An enteroanastomosis diverts the alkaline duodenal secretions away from the gastrojejunal anastomosis. A Murphy button anastomosis creates a small gastrojejunal stoma which will produce a jejunal ulcer in spite of a radical resection. The original Billroth II method with the closure of the cut end of the stomach produces a blind pouch which also creates favorable conditions for a jejunal ulcer. k, There are 5 errors in this operation, any one of which would be sufficient to create favorable conditions for a renewed jejunal ulcer. (1) the gastric remnant is too large. (2) the closure of the distal end of the stomach creates a blind sac. (3) the end-to-side anastomosis creates a small stoma. (4) The enteroanastomosis diverts the alkaline contents from the gastrojejunal anastomosis. (5) the Schmillinsky procedure is most likely to result in a jejunal ulcer and also dyspeptic symptoms from the regurgitation of the duodenal contents into the stomach. l, This is another Schmillinsky procedure which is most likely to bring recurrence of a je-

junal ulcer and also to result in severe dyspeptic symptoms from the regurgitation of bile and pancreatic juice into the stomach. m, The author's proximal "Y" anastomosis with a temporary jejunostomy. Nine such reconstructive procedures resulted in 2 jejunal ulcers. Even if the proximal "Y" anastomosis allows the alkaline duodenal contents to bathe the gastrojejunal anastomosis, its construction requires a longer proximal jejunal loop than in the standard retrocolic method. The proximal "Y" anastomosis is more complicated than the other methods of reconstruction.

9 patients 2 of whom returned with jejunal ulcers. Of the 339 personally performed short afferent loop radical retrocolic gastrectomies not 1 patient returned with a jejunal ulcer

Wangensteen reported 350 short afferent loop subtotal gastrectomies. Of these only 1 patient developed a jejunal ulcer (Figs 1 and 2)

Fig. 3. An analysis of operative procedures which have been used for the cure of jejunal ulcers. a, A split of its correct anatomical relationship, the antecolic resection with a long proximal jejunal loop attached to the greater curvature wall will have a tendency to dump the gastric contents into the proximal jejunal loop. Such an anatomical relationship may cause dyspeptic symptoms and vomiting from the sudden emptying of a dilated proximal jejunal loop into the lumen of the gastric remnant. Many surgeons of experience attach the proximal jejunal loop to the greater curvature because such arrangement allows for no rotation of the jejunum on its axis as in the Hofmeister Finsterer technique where the proximal jejunal loop is attached to the lesser curvature angle. b, An antecolic anastomosis with more than one half of the gastric remnant will not prove as successful in preventing jejunal ulcerations as retrocolic subtotal resection. c, A gastric resection with

an enterocolic anastomosis. An enterocolic anastomosis placed close to the gastrojejunal opening may not have the evil effects of the total diversion of the alkaline duodenal contents. In order to insure against further jejunal ulcerations, no type of enterocolic anastomosis is recommended distal to the gastrojejunal loop anastomosis. d, A gastric resection with a long jejunal loop anastomosis and also an enterocolic anastomosis. e, A duodenojejunal anastomosis will have a tendency to divert the alkaline duodenal contents from the gastrojejunal stoma and, therefore, create favorable conditions for a new jejunal ulcer. f, Another type of a duodenojejunostomy which will also have a tendency to divert the alkaline duodenal contents away from the gastrojejunal anastomosis. This type of reconstructive surgery does not satisfy the physiological concepts for successful gastrectomy.

Before I had the opportunity to witness the technique of gastrectomy performed by two European surgeons of high reputation I was puzzled at their published results which were not as favorable as those reported by Finsterer. One of the two above mentioned surgeons used the original typical retrocolic Billroth II method which produced a blind terminal sac the other surgeon used a long loop antecolic anastomosis. Neither of these surgeons, however, reported his particular technique. My own

disappointing results with the original Finsterer exclusion operation and with the proximal Y anastomosis are of more importance than carefully controlled animal experimentations. Of the 14 patients who had undergone exclusion operation with a radical gastrectomy performed by me 3 returned with jejunal ulcers. Proximal Y anastomoses, in which the gastrojejunal anastomosis was usually placed about as far from the ligament of Treitz as in the antecolic method were performed in

perforated ulcer and a gastroenterostomy. Death was due to massive atelectasis, edema, and fluid in the pleural cavity. Contributing cause in this case was the injudicious use of saline. Death in this case was preventable.

CASE 47. No. 65060 male 38 years old had a gastrectomy for a jejunal ulcer which followed a gastroenterostomy. Death was due to perforation of the transverse suture line in the jejunum and to the injudicious use of too much saline and fluids. Death was preventable.

CASE 48. No. 3846 male 48 years old had a gastrectomy for gastric and duodenal ulcer following 3 operations including a gastroenterostomy. Death was due to shock and gangrene of jejunal loop. Death was preventable.

TABLE III.—REOPERATION FOR JEJUNAL ULCERS FOLLOWING 373 PERSONALLY PERFORMED GASTRECTOMIES (371 PATIENTS)

	No. of gastric tumors	Jejunal ulcers	Per cent jejunal ulcers
Primary and secondary gastrectomies with ulcer either removed or left by various methods (exclusion*) No. patients who survived	119		
Primary and secondary subtotal gastrectomies combined with original Finsterer exclusion operation† No. patients who survived	4	3	7
Subtotal gastrectomies with the proximal Y anastomosis‡ No. patients who survived	0		

*The gastric mucosa was ablated in the distal remaining gastric segment.

†Gastric mucosa was not ablated in remaining distal gastric segment.

‡The proximal jejunal loop was long.

Though a jejunal ulcer may make its appearance many years following any type of gastrojejunal anastomosis, thus far not 1 of the 330 patients with primary and secondary standard short proximal loop retrocolic gastrectomies came to me for reoperation because of a jejunal ulcer. I have learned that 1 of the 330 patients who has had an exclusion operation with the mucosa ablated was reoperated upon elsewhere. It is possible that in this patient a remnant of gastric mucosa has regenerated along the denuded pyloric muscle. Another patient has advised us that he has left to consult a clinic because of epigastric pain and distress.

TABLE IV.—REVIEW OF 373 PRIMARY AND SECONDARY GASTRECTOMIES (371 PATIENTS)

	N	Mortality	Per cent
Primary gastrectomies including operations for acute massive hemorrhage	300	4	1.3
Secondary gastrectomies	73	3	4
Primary and secondary gastrectomies which includes every gastrectomy since 1924	373	7	1.8

All 4 deaths in the group of the primary gastrectomies occurred in patients who were admitted to the hospital for acute massive hemorrhages. All 4 patients were operated

upon several days after admission. Only 2 of the 4 patients came to the operating room with the hemorrhage arrested. One of the 2 died 14 days after the operation from a coronary infarction. The other died from an overlooked perforated duodenal ulcer on the posterior wall. If the 2 fatalities which occurred in those patients who were exsanguinated and who came late for the operation with the hemorrhage unarrested were subtracted the corrected mortality would be reduced to 0.8 per cent, or 2 deaths in 198 primary gastrectomies.

TABLE V.—END-RESULTS IN 71 PATIENTS WITH SECONDARY GASTRECTOMIES

(Period of observation from 1 to 20 years)	No.
Patients having had multiple operations	71
Previous gastric operations in 71 patients	107
All gastric operations in 71 patients	178
Died from the operation in hospital	3
Died later	
Cancer of the stomach	1
Cancer of the prostate	1
Jejunocolic fistula following exclusion operation with mucosa not ablated	1
Not returned for observation	6
Returned for observation	59
Perforated jejunal ulcer following the proximal Y anastomosis (long proximal anastomotic loop)	1
Hemorrhage following the proximal Y anastomosis (long proximal anastomotic loop)	1
Satisfactory results (no pain or hemorrhage)	57

SUMMARY AND CONCLUSIONS

Seventy-one patients with 107 antecedent gastric operations have been subjected to 73 gastrectomies. The most common antecedent gastric operations were gastroenterostomies, pyloroplastics, excision of ulcers, and the various types of atypical gastric resections. Thus far no patient has been operated on for a jejunal ulcer following a radical standard retrocolic resection. Altogether these 71 patients have had 178 gastric operations. Five of the 71 patients with recurrent ulcers were originally operated upon by myself.

An additional 300 patients were subjected to a primary gastrectomy because of a duodenal or gastric ulcer. The 371 patients who have been subjected to a gastrectomy because of a duodenal jejunal or gastric ulcer have had 95 previous gastric operations of various types performed elsewhere.

Mortality. The mortality in 71 patients with secondary gastrectomies was 4.1 per cent in 300 primary gastrectomies, 1.3 per cent and in 373 primary and secondary gastrectomies 1.8 per cent. This does not represent a selected group of patients since it includes all the gastrectomies performed for any type of

OPERATIVE PROCEDURES USED FOR THE CURE OF JEJUNAL ULCERS AND LIKELY TO RESULT IN FAILURE

1 All types of short circuiting operations which divert the alkaline duodenal contents away from the gastrojejunal anastomosis. The outstanding examples of such operations are the original Y anastomosis of Roux and the enteroanastomosis of Braun particularly if the latter is placed some distance from the gastrojejunal anastomosis.

2 Minimal gastrectomy

3 The Schmilinsky operation

4 The various types of the exclusion operation in spite of a radical gastrectomy unless the gastric mucosa is completely ablated. However it is not always possible to know whether the gastric mucosa is completely removed in the Wilmanns modification of the Finsterer exclusion procedure in the presence of induration and edema. A part of the pyloric mucosa may be inverted into the duodenal lumen and it may later regenerate along the muscular walls of the pyloric remnant. This actually happened in 1 of our patients who developed a fistula following this type of exclusion operation. No jejunal ulcer resulted in this instance. In another exclusion procedure with much cartilaginous induration there is reason to believe that not all of the pyloric mucosa was removed. The patient was later operated upon elsewhere presumably for a jejunal ulcer. My modified pyloroplastic closure of the duodenum enables one to remove all of the pyloric mucosa.

5 Gastrectomy with a gastrojejunal anastomosis placed antecolic some distance from the duodenojejunal angle particularly if the resection is minimal.

6 My proximal Y anastomosis.

7 A small gastrojejunal stoma (Murphy button operation) in spite of a major resection.

8 Kinks resulting in jejunal stenosis and stasis proximal or distal to the gastrojejunal anastomosis.

9 The original Billroth II anastomosis which may result in a blind sac distal to the gastrojejunal stoma.

10 Other operations which are likely to prove ineffectual for the cure of jejunal ulcers.

(a) dismantling of the gastroenterostomy
(b) excision of the jejunal ulcer (c) pyloroplasty (d) a new gastroenterostomy and (e) gastroduodenostomy

ANALYSIS OF POSTOPERATIVE DEATHS

There were 4 postoperative deaths in 300 primary gastrectomies and 3 deaths in 73 secondary gastrectomies. The combined operative mortality in 373 primary and secondary gastrectomies was 1.8 per cent. After reporting 117 primary gastrectomies in 1940 with a mortality of 2.6 per cent there followed another group of 163 primary consecutive gastrectomies with 1 death (mortality 0.6). This death occurred in a patient operated on for acute massive hemorrhage from a duodenal ulcer. This analysis of mortality statistics represents no selected group of cases and includes all of the gastrectomies performed for peptic ulcers since 1924. Not a single gastroenterostomy was performed after 1916.

CASE REPORTS OF PATIENTS WHO SUCCEDED FOLLOWING A PRIMARY GASTRECTOMY

CASE 42. A male between 40 and 50 years old was operated upon in a small private hospital for a large bleeding ulcer in the posterior wall of the duodenum which had perforated into the pancreas. The patient expired on the fifth day following the gastrectomy. No blood was available for transfusion in the hospital. The death could be considered as avoidable.

CASE 43. A 8349, male 69 years old had a primary gastrectomy for a bleeding gastric ulcer. Patient died weeks after the operation from a coronary infarctio. This death was unavoidable.

CASE 44. N 4-8156 male 36 years old had a primary gastrectomy for an acutely bleeding ulcer. He had 7 blood transfusions previous to operation. Death was due to an overlooked perforation of a posterior duodenal ulcer caused by a finger which was introduced into the pylorus during the exploration. It is dangerous to force the finger through a stenosed duodenum since it may penetrate the posterior wall without being recognized. This death is to be considered as avoidable.

CASE 45. N B-60712 female 60 years old had a primary gastrectomy for an acutely bleeding ulcer. This death was due to a fulminating enteritis. It is possible that timely and generous use of plasma and blood might have prevented this fatal ty.

FATALITIES FOLLOWING SECONDARY GASTRECTOMIES

CASE 46. N B 54227 male 58 years old had a secondary gastrectomy following an operation for a

other was operated upon for a perforated jejunal ulcer. In spite of the fact that this type of a Y anastomosis allows the alkaline duodenal secretions to bathe the gastrojejunal anastomosis, it places the anastomosis some distance from the duodenojejunal angle. It therefore creates the same potential danger for a new jejunal ulcer as does the antecolic anastomosis. The proximal Y anastomosis with a temporary jejunostomy is also more difficult and time-consuming. It may however find an occasional indication.

Results of radical gastric resection in patients with recurrent peptic ulcerations who were subjected to 107 antecedent gastric procedures of various types which resulted in failure. Three patients died in the hospital, 2 died later from carcinoma, 1 died from a jejunocolic fistula following the Finsterer exclusion operation in which the gastric mucosa was not ablated. Two patients developed jejunal ulcers following my reconstructive gastrectomy with a proximal Y anastomosis. Six patients did not return for the follow up study. Fifty seven patients who have been operated upon for recurrent peptic ulcers and who were observed from 1 to 20 years have thus far, remained free from any symptoms such as epigastric pain or hemorrhage suggestive of jejunal ulcerations.

Prevention of jejunal ulcer. Of the 339 patients upon whom I performed primary and secondary radical gastrectomies of the standard retrocolic type and who were observed from 1 to 24 years, not 1 has returned for reoperation because of a jejunal ulcer. The jejunal ulcers were found following the gastroenterostomy, the exclusion operation, the minimal gastrectomy, the antecolic radical gastrec-

tomy, the short-circuiting operations such as the enteroanastomosis, the gastrectomy with a small stoma, and also the proximal Y anastomosis gastrectomy. The standard radical proximal short loop retrocolic terminolateral gastrectomy with a sufficiently wide stoma gives maximum protection against the dreaded jejunal ulcer. The ulcer diathesis has not been found to be a factor in the recurring jejunal ulcer. Every jejunal ulcer and its recurrence were found to follow the inadequate type of operation.

simple or complicated case since 1924. The last gastroenterostomy was performed in 1926.

Since at least 5 of the 7 deaths were avoidable, the risk of the gastrectomy operation cannot be considered as contingent upon some insurmountable or unpredictable condition but rather on the lack of supreme diligence in the technical execution of the operation or in the preoperative and postoperative care. No patient succumbed to the operation because of the many hours spent on the operating table. With the advent of contemporary supportive treatment during the anesthesia the additional time which the patient spends in the operating room should no longer disturb a considered planning and a considered execution of the operation.

Morbidity. There was not a single serious postoperative hemorrhage. The contents in the drainage bottle are frequently blood stained in the first 24 hours. The double ligation of most of the mesenteric blood vessels and the introduction of hemostatic sutures along the gastrojejunal anastomosis prevents any serious postoperative bleeding.

There were 2 patients with postoperative gastric retention who were operated on. There is reason to believe that these 2 patients would have recovered without additional surgery. There were 2 other patients with gastric retention who recovered without further surgery.

Postgastrectomy symptoms and disabilities. Following the gastrectomy operation the greatest majority of the patients display no serious or disabling symptoms. Such complaints as intolerance to certain foods, the feeling of fullness, perspiration and rapid pulse following the ingestion of a meal, disappear or become less annoying at various periods after the operation. Fatigue, irritability and nervousness are not as common as the postprandial symptoms but these may persist for a longer period. Most of these symptoms also vanish in time. The failure to gain weight is most persistent in a good number of these patients. The postgastrectomy syndrome though at times annoying in a few patients has thus far incapacitated only 1 because of frequent spells of syncope. Thus far no patient has been hospitalized because of the postgastrectomy syndrome.

The exclusion operation. The exclusion operation of Finsterer in which the pyloric mucosa was removed according to the method of Wilmanns resulted in sinus or fistula formation in 7 instances. Of the 14 personally performed radical gastrectomies for duodenal ulcer in which the original Finsterer exclusion operation was employed and the mucosa was not removed 3 patients developed jejunal ulcers. Of the 10 patients with gastrectomies who were originally operated upon elsewhere and who were later reoperated upon by me because of jejunal ulcers, in 8 the original operation represented some type of the exclusion procedure in which the pyloric mucosa was not removed. Even the Wilmanns type of the Finsterer exclusion operation in which the gastric mucosa is removed cannot always be considered as the ideal procedure. In the presence of edema and induration it is not always possible to determine whether all of the gastric mucosa is removed. A remnant of the gastric mucosa may regenerate along the denuded gastric musculature and bring about the same condition for the development of a jejunal ulcer as after the original exclusion operation. The modification of my original pyloroplastic closure of the duodenum prevents such complications.

It still seemed incredible to indict a small fragment of the remaining pyloric mucosa as the sole cause of jejunal ulcerations. The frequency of jejunal ulcers which follow all sorts of exclusion operations (Von Eiselsberg, Devine and Finsterer methods) condemns this procedure and unless it is combined with a major retrocolic short proximal loop gastrectomy. It is not necessary to remove the duodenal ulcer but it is important to be certain that no gastric mucosa is left in the excluded part of the musculature.

Proximal Y anastomosis with temporary jejunostomy. There have been 11 patients who were subjected to secondary gastrectomies by this method. One patient died, another was found to have a gastric carcinoma. Of the 9 remaining patients with jejunal ulcerations who were subjected to the proximal Y anastomosis with a temporary jejunostomy 1 patient had had a gastric hemorrhage about 2 years following the operation and an-

tics to control generalized infections. Properly placed incisions will lessen the frequency of chondritis following operations for the drainage of intrathoracic or upper abdominal suppuration. When an empyema or pulmonary abscess requires drainage it is advisable to resect a portion of rib rather than a cartilage, if such a procedure will provide an adequate approach. When the suppurative area lies beneath the cartilage thus requiring its resection several points should be borne in mind. If one of the upper five cartilages is to be resected the entire cartilage should be removed. For drainage of a suppurative lesion in the middle lobe resection of the fourth or fifth costal cartilage is usually sufficient. The costal arch therefore may be left intact. It is rarely necessary to resect a cartilage below the fifth for intrathoracic drainage anteriorly. Cartilage is often needlessly exposed because the surgeon does not determine the site of the costochondral junction before the rib segment is cut anteriorly. Pricking through the perichondrium with a needle or the point of a clean knife will readily and accurately show where the softer cartilage begins.

If a costal cartilage is partly resected in an infected wound and complete removal of the remainder of that cartilage is considered undesirable the denuded part of the cartilage should be covered by perichondrium. A simple method to accomplish this is to resect the cartilage subperichondrially for about 1 centimeter back of the line of division of the perichondrium. A curette may be used to break off pieces of the cartilage within the perichondrial envelope. The redundant perichondrium is then sutured over the exposed cut surface of the cartilage so as to cover it completely. If other tissue such as muscle is available it may also be employed to cover the cartilage. When incisions are made in the upper abdomen care should be taken that the perichondrium of the lower margin of the costal arch is not exposed if a suppurative focus is being drained. If cartilage is inadvertently denuded it should be well covered with soft tissues preferably muscles and no drainage material should come in contact with it.

Infections of the costal cartilages are likely to become chronic unless certain fundamental

principles of surgical therapy are appreciated. Although chemotherapy plays an important rôle in the treatment of chondritis the problem is predominantly surgical. The surgeon must realize that procedures adequate for the treatment of localized infection in bone do not suffice for the treatment of chondritis. If only the involved portion of the cartilage and diseased soft tissue is removed, persistent sinus formation may occur. The surgical treatment of chondritis is subperichondrial resection of the entire involved cartilage. This principle was clearly demonstrated by Moschowitz. The resection should extend from the bony rib to the bony sternum and not even a small bit of cartilage should be allowed to remain. Whereas this surgical procedure can be readily applied to the cartilages from the first to the fifth inclusive the situation is far more complicated when the chondritis affects the seventh eighth ninth or tenth cartilages. Since these four costal cartilages articulate with each it is not possible to remove one of these cartilages without exposing a portion of denuded cartilage adjacent to it. For this reason radical treatment of chondritis of the seventh to the tenth cartilages involves complete resection of the costal arch with removal of all four cartilages from the rib to the medial termination. Resection of the sixth cartilage may also be necessary because of fusion with the seventh. Whereas this radical procedure is more certain of producing complete and permanent healing than a more localized cartilaginous resection recent personal experience suggests that healing may occur if a flap of viable tissue is sutured over that portion of the adjacent cartilage which is bared of perichondrium and local penicillin therapy is employed. The less radical operation certainly justifies a trial especially in cases in which the patient is in poor general condition or is on the verge of cardiac or respiratory insufficiency. Resection of the costal arch results in considerable abnormal mobility of the thoracic cage temporarily and therefore may be a serious intervention for a patient who has marked pulmonary emphysema or a serious cardiac lesion. In cartilaginous resections for infection care should be taken to avoid injury to the underlying pleura.

INFECTIONS OF THE COSTAL CARTILAGES AND STERNUM

HERBERT C. MAIER, M.D. F.A.C.S. New York, New York

INFECTIONS of the costal cartilages and sternum present special problems in surgical treatment. Although the advent of chemotherapy has lessened the frequency and severity of suppuration of the chest wall, costal chondritis and sternal osteomyelitis still not infrequently require operative intervention. If the special problems concerned with the surgical management of infections of the costal cartilages and sternum are not properly understood, the results are often unsatisfactory and complete healing fails to occur. The present communication is concerned therefore with an analysis of the subject on the basis of personal experience and a review of the literature. A few illustrative cases are presented in detail.

INFECTION OF THE COSTAL CARTILAGES

The special problems associated with infection of the costal cartilages are due to certain characteristics of hyaline cartilage as well as to the anatomic arrangement of these cartilages forming the anterior thoracic wall. Hyaline cartilage does not contain any blood vessels or nerves and derives its nutrition from the lymph. Because of its avascularity, this tissue is very vulnerable to infection. When denuded of its perichondrium and left exposed in an infected wound, cartilage acts much like a foreign body. When only a portion of a cartilage is resected, the cut surface of the remaining segment is not covered by perichondrium. Similarly, removal of only one of two or more fused cartilages will leave an area denuded of perichondrium at the site of fusion. Whenever a piece of cartilage, any part of which is denuded of perichondrium, projects into an infected wound, a persistent sinus may occur. Only if infection is minimal or the exposed part of the cartilage is covered with viable tissue before the necrosis begins, can sinus formation be avoided. In clean wounds, however, partial resection of cartilages may be done.

The upper seven ribs are connected to the sternum by costal cartilages which are a direct bridge between the anterior end of the bony rib and the sternum. The perichondrium encasing the cartilages is continuous with the periosteum of the rib. Fusion between any of the upper five cartilages is rare. The sixth and seventh cartilages sometimes articulate with each other lateral to the sternum. The eighth, ninth, and tenth cartilages do not reach as far as the sternum, but end in the lower margin of the preceding cartilage. The seventh to the tenth costal cartilages inclusive constitute the costal arch. It is usually possible, therefore, to remove one of the upper five cartilages without denuding the adjacent cartilage of its perichondrium. Exposed cartilage would project into the wound, however, if only one of the seventh, eighth, ninth, or tenth cartilages were removed, since each of these, and sometimes the sixth, has an area of fusion with the adjacent cartilage.

Chondritis due to pyogenic organisms may occur as a result of wounds, as a direct extension from an adjacent infection following operation for drainage of suppurative foci, and as a result of systemic infection. The staphylococcus and streptococcus are the most frequent pyogenic organisms found in costal chondritis. In past years, however, the typhoid and paratyphoid organisms were not infrequent causes of chondritis. Tuberculous involvement of the cartilages is still common, but the process is usually secondary to tuberculosis of adjacent structures, especially the pleura and the mediastinal lymph nodes. Various fungi, particularly actinomyces and blastomyces, may be the cause of chondritis. Extensive wound infection following radical mastectomy may result in costal chondritis and even osteomyelitis of the sternum.

The incidence of chondritis and perichondritis will undoubtedly be considerably diminished by the use of sulfonamides and antio-

may be secondary to disease originating with in the mediastinum. There is a high incidence of pulmonary complications associated with sternal osteomyelitis.

The treatment of sternal osteomyelitis consists of chemotherapy and resection of the involved portion of the sternum. If the osteomyelitis of the sternum is localized the diseased portion may be readily removed with the rongeur. Care must be taken to avoid injury to the pleura and the underlying mediastinal structures. In some instances the posterior periosteum may be preserved. If the sternal involvement is very extensive and especially if the patient has impaired cardiac or respiratory function, it may be advisable to perform the operation in stages in order to lessen the temporary abnormal mobility of the thoracic cage. In some cases the paradoxical motion of the chest wall is lessened as the result of the inflammation of the soft tissue. In 1 of my cases there was clinical evidence of involvement of the sternoclavicular joints but penicillin therapy resulted in subsidence of the infection without surgical intervention. The possibility of an anterior mediastinal abscess in association with substernal osteomyelitis must be borne in mind. Care should be taken to avoid needless entry into the mediastinal tissues. Because resections of the sternum for osteomyelitis are usually incomplete some bony regeneration occurs and provides stability of the anterior portion of the thorax after the postoperative period.

ILLUSTRATIVE CASES

CASE 1. A. E. female, aged 64 years had a carcinoma of the right breast complicated by diabetes mellitus and cardiac decompensation. A radical mastectomy was performed under local anesthesia in November 1943. Infection of the operative wound with *Staphylococcus aureus* followed. In January 1944 a portion of the third rib and cartilage was resected and the following month portions of the fourth and fifth ribs and cartilages were resected. It should be noted that only parts of the costal cartilages were removed in each instance. The infection of the chest wall progressed. Sulfonamide therapy and penicillin were given without avail. In March 1944 when the patient first came under my observation at Memorial Hospital there was an extensive suppurating wound in the anterior portion of the chest wall. There was obvious chondritis of several of the costal cartilages on both the right and left side. There was marked tenderness over the entire sternum and over

Fig. 1, left. Infected mastectomy wound with costal chondritis and sternal osteomyelitis.

Fig. 2. Healed wound after multiple operative procedures for bilateral costal chondritis with sternal osteomyelitis.

both sternoclavicular joints. The patient had high fever and was obviously acutely ill. A diagnosis of multiple suppurative chondritis osteomyelitis of the sternum and sternoclavicular arthritis was made (Fig. 1). Because the patient was on the verge of cardiac decompensation it was most important to avoid any respiratory difficulty such as might follow paradoxical motion caused by extensive resection of the chest wall in one stage. Multiple stage operations were therefore undertaken. Systemic and local penicillin therapy was also employed. In the course of 4 operative procedures spaced over a period of several months most of the costal cartilages on the right, the body of the sternum and some of the costal cartilages on the left side were removed. In addition punch grafts were employed because of the large skin defect. At the first operative procedure the soft tissue abscesses especially the large abscess overlying the body of the sternum were drained and some of the resected cartilages on the right side were completely excised. At the second stage operation the entire body of the sternum was resected and at the third procedure the right costal arch was resected with removal of the sixth seventh eighth ninth and tenth costal cartilages. Following these procedures the entire area healed with the exception of two persistent sinuses one near the lower end of the manubrium and the other leading to the fourth left costal cartilage. This costal cartilage was then removed in its entirety and healing of the entire wound finally occurred (Fig. 2). There was good stability of the chest wall without any paradoxical motion on respiration.

If the infected costal cartilages had been radically removed at an early stage of the thoracic wall suppuration it is quite likely that extensive spread of the infection, especially into the body of the sternum and across to the opposite side might have been avoided.

Infections of the costal arch of one side may extend to the opposite side either through involvement of the xyphoid process or as a result of secondary osteomyelitis of the sternum. The xyphoid process is cartilaginous in early life but becomes partly ossified in adults. The risk of involvement of the xyphoid is greater when the structure is chiefly cartilaginous. An example of the drastic complications that may follow infection of the costal arch occurring as a sequela of the drainage of a subphrenic abscess is illustrated in a case reported by Siler. The patient developed chondritis of the left costal arch which required radical operation. The infection spread from the left to the right costal region through the cartilaginous tissue of the xyphoid process. In spite of further surgery the process extended upward so that three more operations were required with the result that eventually all twenty costal cartilages and the entire sternum were resected. It should be noted that the patient had serious respiratory difficulty in the postoperative period following the last procedure.

Following subperichondrial resection of a cartilage osseous tissue may develop and result in the formation of a rigid structure (1). If the perichondrium is sacrificed in the removal of a cartilage a permanently flaccid area in the chest wall will result. Unless care is taken to preserve the perichondrium extensive removal of the cartilaginous structures of the chest wall will result in an undesirable instability of the thoracic cage. The formation of osseous tissue after subperichondrial resection of cartilage is well illustrated in Figure 4. Plastic procedures of varying magnitude may be required to obtain complete healing if there has been much loss of skin due to severe infection.

OSTEOMYELITIS OF THE STERNUM

Osteomyelitis of the sternum as a result of septicemia is an uncommon occurrence (4) and constitutes only $\frac{1}{3}$ of 1 per cent of all forms of osteomyelitis. Considerably more common is involvement of the sternum as the result of direct extension of infection from adjacent areas. Osteomyelitis of the sternum is often secondary to costal chondritis. Because

of the relative infrequency of operative procedures which involve direct exposure of the sternum osteomyelitis is rarely seen as a result of infected wounds of the chest wall except when the infection has extended from adjacent structures, such as the costal cartilages. The incidence of osteomyelitis of the sternum can therefore be drastically reduced by proper early treatment of costal chondritis. The bacteriological findings in sternal osteomyelitis and costal chondritis are similar.

The clinical picture of osteomyelitis of the sternum resembles that of involvement of other bony structures. When the infection is due to pyogenic organisms there are usually systemic signs of infection combined with local tenderness, swelling and perhaps fluctuation. Roentgen examination is usually of little aid in the early diagnosis of sternal osteomyelitis but is occasionally helpful in the more chronic stage of the disease. Lateral and oblique views are most satisfactory for roentgen visualization of the sternum. The absence of changes on the roentgenogram does not exclude an extensive osteomyelitic process. If the involvement of the sternum is due to the tubercle bacillus there may be little pain or tenderness and a cold abscess may be the presenting sign. A tuberculous abscess overlying the sternum does not necessarily indicate involvement of the underlying bone. The tuberculous process may have arisen in the mediastinum and broken through the interspace lateral to the sternum and then extended superficially to the midline. There may be difficulty in distinguishing between chronic osteomyelitis and a tumor of the sternum. When the sternum has been destroyed by a pyogenic or neoplastic process, the pulsation of the underlying great vessels may be transmitted to the skin and closely simulate an aneurysm. Gumma of the sternum must be considered in the differential diagnosis.

When sternal osteomyelitis occurs as a result of septicemia, the mortality rate is much higher than when the infection has extended from adjacent costal cartilages. Anterior mediastinal abscess may occur in association with sternal osteomyelitis, due to the infection breaking through the posterior pericostum. Occasionally the sternal involvement

This case is one of osteomyelitis of the sternum as part of a general septicemia. The destruction of the sternum was unusually rapid. The pulsation of the abscess overlying the sternum was so pronounced that some observers thought it might be an aneurysm. The anterior mediastinal abscess and pneumonia which were present in this case are two of the common complications of an osteomyelitis of the sternum and are associated with a high mortality. Death in this case was undoubtedly due to uncontrolled suppurative foci elsewhere. Osteomyelitic involvement of the sternum at the synchondrosis between the manubrium and gladiolus is uncommon.

CASE 3 B. M. male aged 51 years was stabbed in the chest near the junction of the second costal cartilage and the left border of the sternum. When admitted to the thoracic service of Kings County Hospital a week after injury, the patient was dyspneic, cyanotic, and disoriented. The wound discharged a foul pus. There was fluid in the left pleural cavity and within the pericardium. An abscess of the chest wall at the site of the stab wound was incised and drained. The culture from this abscess grew out *Staphylococcus aureus*. Thoracentesis of the left pleural space yielded thick pus containing staphylococci, and the bloody fluid obtained on pericardial tap also yielded hemolytic *Staphylococcus aureus*. The empyema and suppurative pericarditis were treated by aspiration and direct instillation of penicillin into the pleural and pericardial cavities respectively. The patient's condition improved progressively. The empyema and pericarditis cleared without surgical intervention but the original infected stab wound continued to drain. Probing of this wound demonstrated the presence of necrotic bone and therefore operation was undertaken for suppurative osteomyelitis and chondritis. The partly infected second costal cartilage was completely removed and the involved portion of the sternum in the same region was resected with a rongeur. There was no evidence of a mediastinal abscess. Following this procedure the patient made an uneventful recovery and the wound was healed a little over a month later.

This patient had an extensive staphylococcus infection involving two serous cavities which responded to penicillin and sulfonamide therapy. The local wound failed to heal however because of the involvement of bone and cartilage. Following surgical removal of the osteomyelitic portion of the sternum and the entire involved cartilage healing occurred without further incident.

CASE 4 A. K. male, aged 38 years. When the patient was first seen at Bellevue Hospital in Decem-

ber 1940 he gave a history of having had repeated abscesses in the right lower anterior thoracic region for 19 years. Although the abscesses were opened surgically on a few occasions they usually ruptured spontaneously and sinuses persisted for varying periods of time. In December 1940 there was a large fluctuating area overlying the right costal arch with skin necrosis. A large superficial abscess was drained. Lipiodol injection of the sinus tract revealed an abscess cavity extending beneath the costal arch but not communicating with the pleural cavity. In January 1941 a radical resection of the entire costal arch was performed with removal of the sixth through the tenth costal cartilages inclusive from the rib to the sternum. The postoperative course was uneventful but the wound granulated in slowly because of the large skin loss caused by the previously neglected superficial abscess. In December 1941 the patient complained of tenderness and pain in the region of the lower end of the sternum. Roentgenograms suggested osteomyelitis of the lower sternum. Operation was again performed and the lower end of the sternum and some regenerated bone at the site of the previously resected cartilages were removed. A sinus tract was followed inward and a chronic abscess was found overlying the upper portion of the pericardium. Pathological examination of the wall of the abscess showed only chronic inflammation. All pathological material obtained during the various operative procedures showed nonspecific inflammation. Tuberculosis was never demonstrated. The operative wound healed gradually except for one small sinus. About this time the patient had recurrent attacks of cholecystitis. In August, 1942, cholecystectomy was performed for cholecystitis and cholelithiasis. Since that time the patient has had no further symptoms referable to the biliary tract.

The small sinus which persisted in the anterior thoracic region would sometimes close for several weeks and then reopen spontaneously. The patient also had some cough productive of mucopurulent sputum and several attacks of pneumonitis. Lipiodol injected into the sinuses entered the tracheobronchial tree and demonstrated the presence of a bronchocutaneous fistula (Fig 3). Bronchograms showed bronchiectasis of the right middle lobe. Therefore in May 1944, another operation was undertaken. Through a posterolateral incision on the right the pleural cavity was entered. The middle lobe was found to be a dense fibrotic mass. It was firmly adherent to the mediastinum and pericardium at the site of the old mediastinal abscess. The middle lobe communicated with the chest wall sinus. A middle lobe lobectomy was performed. There was marked infiltration of the anterior thoracic wall in the region of the thoracic sinus, and several cubic centimeters of thick yellow, nonodorless pus was present. The operative wound healed by primary union except at the site of drainage. This area did not heal permanently for nearly 4 months. All wounds have remained healed the patient now 2½ years later has no cough or sputum and is in excellent condition.

Fig. 3. (left, Posteroanterior film. b, Lateral film. Lipiodol injected fist sinus at lower right border of sternum has entered the right middle lobe through a previously unsuspected bronchocutaneous fistula. There is bronchiectasis of the right middle lobe. Some lipiodol has pulled over into the left lung.

Failure to appreciate the importance of complete removal of an infected costal cartilage was at least partly responsible for the serious situation which developed.

CASE 2. F McV. (male aged 19 years gave a history of cough and chest pain of 13 days duration. The onset began with a severe sore throat, fever, dysphagia, and progressive prostration. Substernal pain was noted 5 days later. The cough was produc-

Fig. 4. X-ray film taken 1 year after resection of the costal arch shows bone formation at the site of the previously resected cartilages.

tive of rusty sputum. Sulfonamide therapy had been given without response. On admission to Kings County Hospital the patient was acutely ill, markedly dyspneic, somewhat disoriented and icteric. There were dullness and rales at the bases of both lungs. A soft, fluctuant, raised area was present over the sternum at the junction of the manubrium and gladiolus. The cardiac pulsation was transmitted through the mass. Three days after admission crepitation was evident at the junction of the manubrium and gladiolus. Aspiration of the abscess revealed thin, light brown, nonodoriferous pus which cultured hemolytic streptococci. On incision and drainage an abscess cavity overlying the lower portion of the manubrium and upper portion of the gladiolus was found. There was complete interruption of the continuity of the sternum at the site of the synchondrosis. A fairly large anterior mediastinal abscess communicated directly with the site of involvement of the sternum. A small amount of the involved manubrium and gladiolus was removed with a rongeur. Although the second costal cartilage on each side projected into the abscess cavity these two cartilages were not completely removed at this time because of the patient's very poor condition. Following operation the wound drained profusely. The patient showed slight signs of improvement, but the blood culture continued to be positive for hemolytic streptococci in spite of continued penicillin and sulfonamide therapy. The liver was enlarged and tender and the icterus progressed. Two days following operation the patient coughed up a large amount of bright red blood and died very suddenly. It is thought that the bleeding occurred from the rupture of a suppurative intrapulmonary focus because no blood appeared in the operative wound. No autopsy was obtained.

This case is one of osteomyelitis of the sternum as part of a general septicemia. The destruction of the sternum was unusually rapid. The pulsation of the abscess overlying the sternum was so pronounced that some observers thought it might be an aneurysm. The anterior mediastinal abscess and pneumonia which were present in this case are two of the common complications of an osteomyelitis of the sternum and are associated with a high mortality. Death in this case was undoubtedly due to uncontrolled suppurative foci elsewhere. Osteomyelitic involvement of the sternum at the synchondrosis between the manubrium and gladiolus is uncommon.

CASE 3 B. M. male aged 51 years was stabbed in the chest near the junction of the second costal cartilage and the left border of the sternum. When admitted to the thoracic service of Kings County Hospital a week after injury the patient was dyspneic, cyanotic, and disoriented. The wound discharged a foul pus. There was fluid in the left pleural cavity and within the pericardium. An abscess of the chest wall at the site of the stab wound was incised and drained. The culture from this abscess grew out *Staphylococcus aureus*. Thoracentesis of the left pleural space yielded thick pus containing staphylococci, and the bloody fluid obtained on pericardial tap also yielded hemolytic *Staphylococcus aureus*. The empyema and suppurative pericarditis were treated by aspiration and direct instillation of penicillin into the pleural and pericardial cavities respectively. The patient's condition improved progressively. The empyema and pericarditis cleared without surgical intervention but the original infected stab wound continued to drain. Probing of this wound demonstrated the presence of necrotic bone and therefore operation was undertaken for suppurative osteomyelitis and chondritis. The partly infected second costal cartilage was completely removed and the involved portion of the sternum in the same region was resected with a rongeur. There was no evidence of a mediastinal abscess. Following this procedure the patient made an uneventful recovery and the wound was healed a little over a month later.

This patient had an extensive staphylococcus infection involving two serous cavities which responded to penicillin and sulfonamide therapy. The local wound failed to heal however, because of the involvement of bone and cartilage. Following surgical removal of the osteomyelitic portion of the sternum and the entire involved cartilage healing occurred without further incident.

CASE 4 A. K. male, aged 38 years. When the patient was first seen at Bellevue Hospital in Decem-

ber 1940 he gave a history of having had repeated abscesses in the right lower anterior thoracic region for 19 years. Although the abscesses were opened surgically on a few occasions, they usually ruptured spontaneously and sinuses persisted for varying periods of time. In December 1940 there was a large fluctuating area overlying the right costal arch with skin necrosis. A large superficial abscess was drained. Lipiodol injection of the sinus tract revealed an abscess cavity extending beneath the costal arch but not communicating with the pleural cavity. In January 1941 a radical resection of the entire costal arch was performed with removal of the sixth through the tenth costal cartilages inclusive, from the rib to the sternum. The postoperative course was uneventful but the wound granulated in slowly because of the large skin loss caused by the previously neglected superficial abscess. In December 1941 the patient complained of tenderness and pain in the region of the lower end of the sternum. Roentgenograms suggested osteomyelitis of the lower sternum. Operation was again performed and the lower end of the sternum and some regenerated bone at the site of the previously resected cartilages were removed. A sinus tract was followed inward and a chronic abscess was found overlying the upper portion of the pericardium. Pathological examination of the wall of the abscess showed only chronic inflammation. All pathological material obtained during the various operative procedures showed nonspecific inflammation. Tuberculosis was never demonstrated. The operative wound healed gradually except for one small sinus. About this time the patient had recurrent attacks of cholecystitis. In August 1942, cholecystectomy was performed for cholecystitis and cholelithiasis. Since that time the patient has had no further symptoms referable to the biliary tract.

The small sinus which persisted in the anterior thoracic region would sometimes close for several weeks and then reopen spontaneously. The patient also had some cough productive of mucopurulent sputum and several attacks of pneumonitis. Lipiodol injected into the sinus entered the tracheobronchial tree and demonstrated the presence of a bronchocutaneous fistula (Fig 3). Bronchograms showed bronchiectasis of the right middle lobe. Therefore in May 1944 another operation was undertaken. Through a posterolateral incision on the right the pleural cavity was entered. The middle lobe was found to be a dense fibrotic mass. It was firmly adherent to the mediastinum and pericardium at the site of the old mediastinal abscess. The middle lobe communicated with the chest wall sinus. A middle lobe lobectomy was performed. There was marked infiltration of the anterior thoracic wall in the region of the thoracic sinus and several cubic centimeters of thick yellow nonodorous pus was present. The operative wound healed by primary union, except at the site of drainage. This area did not heal permanently for nearly 4 months. All wounds have remained healed the patient now 2½ years later has no cough or sputum and is in excellent condition.

This case is an example of infection of the costal cartilages and sternum secondary to chronic disease of the anterior mediastinum. Tuberculous lymphadenitis may have been the underlying factor although the etiology was never proved. There was considerable calcification present in the hilar lymph nodes. The infection of the structures of the chest wall recurred as long as the underlying intrathoracic suppuration remained. The pulmonary involvement with bronchocutaneous fistula further complicated the situation.

SUMMARY

1 If any portion of one of the upper five costal cartilages is the seat of a suppurative chondritis, surgical removal of the entire cartilage from rib to sternum is indicated. If no chondritis is present but a portion of the normal costal cartilage has been resected in an infected wound the cut surface of the cartilage should be covered by perichondrium.

2 If any portion of the sixth seventh eighth ninth, or tenth costal cartilages is the seat of suppurative chondritis, the entire involved cartilage or cartilages should be removed and a flap of perichondrium and muscle

sutured over the area or areas of adjacent cartilages denuded of perichondrium. Local penicillin therapy should be employed. Should these conservative measures fail or should the initial involvement of the costal arch be fairly extensive radical removal of the entire arch is indicated.

3 Osteomyelitis of the sternum can usually be avoided by adequate early treatment of the infection in the adjacent costal cartilages. Most infections of the sternum begin in the adjacent structures and extend to the sternum secondarily. If osteomyelitis of the sternum develops only the diseased portion of bone need be removed.

4 If extensive osteomyelitis of the sternum exists, the operative procedure for removal of the diseased bone should usually be done in stages to minimize serious abnormal mobility of the chest wall. The possibility of an anterior mediastinal abscess must be borne in mind.

THE ESTIMATION OF ACUTE BLOOD LOSS BY THE TILT TEST

D M GREEN M.D. and DAVID METHENY M.D. F.A.C.S., Seattle, Washington

THE fundamental therapeutic problem in hemorrhage other than direct arrest of bleeding is the determination of the amount of blood required to restore circulatory volume to normal.

An acute blood loss exceeding 40 per cent is likely to be fatal (1, 2). Lesser grades of bleeding may be compensated by vasoconstriction, hemodilution and maintenance of cardiac output through tachycardia. Replenishment of proteins and cells follows more slowly (4).

In the absence of acute bleeding, reductions as great as 80 per cent in hemoglobin and 60 per cent in serum proteins may be encountered in ambulatory patients who present few evidences of critical illness. In hemorrhage, therefore, the major hazard is a decrease in circulatory volume which exceeds the limits of compensability. Attendant disturbances in oxygen carrying capacity, blood viscosity and osmotic pressure are not directly responsible for fatalities. A successful outcome depends fundamentally on the maintenance of an adequate blood volume, regardless of etiology, location or surgical remediability of the hemorrhage.

Direct measure of blood loss rarely is possible. The patient's concept of the quantity is unreliable and vomited or defecated blood is diluted with variable amounts of other fluids. Retention within body cavities or tissues may conceal all external evidences of bleeding (7).

The appraisal of hemorrhage by the red count, hemoglobin and hematocrit values is subject to two sources of error. These values are reduced by preexisting anemia, despite negligible acute blood loss and are unaffected by massive hemorrhage until hemodilution has occurred.

Pulse rate and blood pressure also are used as criteria of severity (6). Frequently, however, no individual base line standards are available. Pulse rates are influenced by fear and by antecedent disease, particularly in the heart. Blood pressure levels within normal limits may represent materially reduced values for the hypertensive patient, while relatively low levels have lessened significance in the hypotensive person.

Ideally, it would be desirable to estimate the severity of hemorrhage by direct measurement of the remaining blood volume (7). However, this procedure has not found common use in the three decades which have elapsed since the introduction of dye methods, apparently because it is too time-consuming or technically difficult for routine clinical practice.

Finally, where the presence of obvious shock indicates a hemorrhage of major proportions, the amount of blood to be given still remains the fundamental problem.

The amelioration of frank hemorrhagic shock by the head-down position is a matter of common experience. Less familiar perhaps is the contrary phenomenon that hemorrhage patients who are able to maintain a relatively normal blood pressure while lying flat, often may be thrown into shock on sitting or standing up (8, 11). The frequency with which these effects may be observed suggested the possibility that cardiovascular reactions to change in posture could be related quantitatively to blood loss and diminished circulatory volume. Accordingly, determinations were made under standardized conditions of the normal response to tilting and its modification by old age, cardiovascular disease, and anemia. Subsequently, the tilting reactions which followed controlled acute blood loss of varying amount were compared with those manifested by a series of patients who were admitted because of recent gastrointestinal hemorrhage.

THE ESTIMATION OF ACUTE BLOOD LOSS BY THE TILT TEST

D M GREEN M D and DAVID METHENY M D, F.A.C.S Seattle Washington

THE fundamental therapeutic problem in hemorrhage, other than direct arrest of bleeding, is the determination of the amount of blood required to restore circulatory volume to normal

An acute blood loss exceeding 40 per cent is likely to be fatal (1 2) Lesser grades of bleeding may be compensated by vasoconstriction hemodilution and maintenance of cardiac output through tachycardia. Replenishment of proteins and cells follows more slowly (4)

In the absence of acute bleeding reductions as great as 80 per cent in hemoglobin and 60 per cent in serum proteins may be encountered in ambulatory patients who present few evidences of critical illness. In hemorrhage, therefore the major hazard is a decrease in circulatory volume which exceeds the limits of compensability Attendant disturbances in oxygen carrying capacity blood viscosity and osmotic pressure are not directly responsible for fatalities. A successful outcome depends fundamentally on the maintenance of an adequate blood volume regardless of etiology location or surgical remediability of the hemorrhage.

Direct measure of blood loss rarely is possible The patient's concept of the quantity is unreliable and vomited or defecated blood is diluted with variable amounts of other fluids. Retention within body cavities or tissues may conceal all external evidences of bleeding (7)

The appraisal of hemorrhage by the red count hemoglobin and hematocrit values is subject to two sources of error These values are reduced by preexisting anemia despite negligible acute blood loss and are unaffected by massive hemorrhage until hemodilution has occurred

Pulse rate and blood pressure also are used as criteria of severity (6) Frequently however no individual base line standard is available Pulse rates are influenced by age and by antecedent disease particularly in the heart. Blood pressure levels within normal limits may represent materially reduced values for the hypertensive patient, while relatively low levels have lessened significance in the hypotensive person

Ideally it would be desirable to estimate the severity of hemorrhage by direct measurement of the remaining blood volume (7) However this procedure has not found common use in the three decades which have elapsed since the introduction of dye methods apparently because it is too time-consuming or technically difficult for routine clinical practice

Finally where the presence of orthostatic shock indicates a hemorrhage of major proportions the amount of blood to be given still remains the fundamental problem.

The amelioration of frank hemorrhagic shock by the head-down position is a matter of common experience Less familiar perhaps is the contrary phenomenon that hemorrhagic patients who are able to maintain a relatively normal blood pressure while lying flat may be thrown into shock on sitting or standing up (8 11) The frequency with which these effects may be observed suggests the possibility that cardiovascular reaction to change in posture could be related quantitatively to blood loss and diminished circulatory volume. Accordingly determinations were made under standardized conditions of normal response to tilting and its modification by old age cardiovascular disease and anemia Subsequently the tilting test which followed controlled acute blood loss of varying amount were compared and manifested by a series of patients recently admitted because of recent gastrointestinal hemorrhage.

Fig. Responses to tilting in normal subjects and in the presence of old age, cardiovascular disease, and anemia. a Normal group, 25 subjects b, aged group, 3 subjects, average age 80 years, c, cardiac group, 11 subjects, d, normal group, 11 subjects, average hemoglobin 7.5 grams.

TILT TEST

The response to tilting was determined as follows. The subject was moved in a supine position to the x ray department of the hospital and placed horizontally on the fluoroscopy table. Pulse rate and blood pressure measurements were made and repeated until constant. Stable readings were obtained within three trials. The table then was tilted to minus 30 degrees, plus 30 degrees and plus 75 degrees and similar measurements carried out. Finally the subject was maintained in a position of plus 75 degrees for 3 minutes and the pulse rate and blood pressure were determined at intervals of 1 minute unless the occurrence of syncope dictated the interruption of the test.

TABLE I—SUPINE PULSE RATES FOLLOWING ACUTE BLOOD LOSS AS COMPARED WITH THE RANGE OF VARIATION IN NONBLEEDING PATIENTS

	Normal	Aged	Cardiac	Anemic	Total non-bleeding	Venesection 9-9 c. kg	Venesection 9-14 c. kg	Venesection 15-20 c. kg	Recent gastro-intestinal hemorrhage
No. of subjects	5	3	11	3	56	9	11	5	11
Average rate	76	87	84	87	84	8	85	95	90
S.D.		9	6	5	7	5	12	5	24

*Standard deviation, corrected for small samples

The responses of practical significance were the ones observed at plus 75 degrees as compared with those at 0 degrees.

Responses to tilting in normal subjects The responses of a group of 25 normal subjects varying in age from 18 to 46 years (Fig 1a) are typical of those described in standard texts of physiology (1). Tilting was marked by a small consistent cardiac acceleration slight fall in systolic pressure and a moderate rise in diastolic pressure. No unusual subjective changes were reported.

Responses to tilting in the aged Observations were made on a group of 13 individuals with a mean age of 80 years (Fig 1b). The group differed from the normal in displaying a higher mean level of pulse rate and systolic pressure while supine. On tilting changes in pulse rate were not marked. The blood pressures varied moderately averaging a small net systolic and diastolic fall.

Responses to tilting in the presence of cardiovascular disease Reactions to tilting were studied in a group of 11 individuals suffering from cardiovascular diseases (Fig 1c). The majority of these patients belonged in the arteriosclerotic or hypertensive classifications and were decompensated in varying degree. The supine levels of pulse and systolic pressure were somewhat above normal. On tilting all circulatory changes were small and inconsistent.

Responses to tilting in the presence of chronic anemia Tilting responses were measured in 13 patients presenting anemia as an intercurrent feature of a variety of disease conditions including metastatic carcinoma, nephritis, subacute bacterial endocarditis and meliorrhagia (Fig 1d). The hemoglobin value varied from 5 to 11 grams, the average being 7.8 grams.

Fig. 2. Dominant responses to tilting in normal subjects before and subsequent to rapid blood loss by venesection. a, Normal, 25 subjects b blood loss, 5 to 9 c.c./kg primary reaction, 17 of 19 subjects c, blood loss, 9 to 14 c.c./kg primary reaction, 9 of 11 subjects, d, blood loss, 14 to 21 c.c./kg secondary reaction, 4 of 5 subjects

Fig. 3. Progression of tilting response in same subject from primary to secondary type with increasing blood loss. Subject T weight 73 kilograms. a, Before venesection b blood loss, 1000 c.c. primary reaction c, blood loss, 1500 c.c. secondary reaction

The increase in pulse rate with tilting was comparable to that noted in normal individuals but the actual rates were higher. A fairly consistent but moderate drop in systolic pressure was observed. Diastolic variations were inconstant, averaging a small net fall. One subject complained of slight dizziness upon being maintained in the plus 75 degrees position. Abnormality of response roughly paralleled the severity of the anemia.

The trend suggests that the stress of tilting is less adequately compensated in the presence of anemia but the observed variations were not statistically significant. This trend may be associated with the decreased peripheral resistance and augmented resting cardiac output observed in anemia, manifestations which can be corrected by transfusion (2).

Responses to tilting following rapid removal of known quantities of blood. Tilting responses were measured in three groups of normal individuals before and immediately following rapid removal of blood by venesection. The subjects consisted of blood donors, residents, interns and hospital orderlies who volunteered their services. Five to 9 cubic centimeters per kilogram were withdrawn from the

19 subjects in group I, 9 to 14 cubic centimeters per kilogram from the 11 subjects in group II and 14 to 21 cubic centimeters per kilogram from the 5 subjects in group III, corresponding respectively to 500, 1000 and 1500 cubic centimeters for the average individual. The time which elapsed between start of venesection and completion of posthemorrhagic tilting varied from 30 minutes to 1 hour depending on the quantity of blood withdrawn.

During and following venesection blood pressures were maintained within normal limits and no unusual subjective reactions were reported as long as the patients remained in the supine position. Comparison of pulse rates with those recorded prior to bleeding indicated that cardiac acceleration was not marked, averaging plus 3, plus 7, and plus 17 beats per minute respectively for the three groups. The actual pulse rates failed to show statistically significant differences in range from those observed in nonbleeding groups (Table I).

On tilting two types of reaction were observed. The primary type and the dominant response in which the blood loss did not exceed 14 cubic centimeters per kilogram was char-

Fig. 4. Reactions to tilting in patients admitted for recent gross gastrointestinal bleeding. Normal response 3 subjects, hematocrit (av.) 37 per cent. b, primary reaction, 3 subjects, hematocrit () 30 per cent. secondary reaction, 6 subjects, hematocrit (a) 29 per cent.

acterized by a well marked cardiac acceleration without significant variation from the systolic pressure drop and diastolic rise associated with tilting normal subjects. The cardio-acceleration on tilting was proportional to the extent of blood loss and averaged 20 beats per minute in group I 42 per minute in group II (Fig. 2b and 2c). Those individuals who had lost the larger quantities of blood showed somewhat increased respiratory depth and definite pallor.

A secondary type of reaction to tilting was observed in 2 of the 19 subjects in group I 2 of the 11 in group II and 4 of the 5 in group III. In these individuals, maintenance in the plus 75 degree position was accompanied by marked tachycardia, air hunger and faintness, succeeded by a rapidly progressive fall in blood pressure to shock levels slowing of the pulse rate ashen pallor cold sweat unconsciousness and transient muscular twitches (Fig. 2d). This type of response was reversible immediately on lowering the subject to the supine position although slow pulse rates sometimes persisted for periods up to several hours.

The primary type of reaction appears to represent a blood volume deficit which is still compensable under the stress of tilting. The

Fig. 5. Tilting responses following acute blood loss (1000 cc) with return to normal on hemodilution. Time interval 1 to 72 hours. a, Primary reaction of tachycardia 5 subjects, hematocrit () 46 per cent. b, return to normal following hemodilution 5 subjects, hematocrit (a) 38 per cent. secondary reaction of syncope 3 subjects, hematocrit (a) 49 per cent. d, return to normal following hemodilution, hematocrit () 38 per cent.

secondary response occurs when this additional stress causes a break in compensation. The relation is illustrated in Figure 3 which depicts the progression from the primary to secondary response in the same individual on withdrawal of an additional 500 cubic centimeters of blood following an initial venesection of 1000 cubic centimeters.

The mechanism responsible for posthemorrhagic syncope on tilting to the upright position is not entirely clear. However a change from supine to upright posture lowers the cardiac output in normal individuals approximately 25 per cent presumably due to reduced venous return secondary to pooling of blood in the extremities (10). This reduction superimposed on the diminished venous return due to hemorrhage may produce a net fall in intracardiac pressure below the critical level for ventricular filling with rapidly progressive circulatory failure cerebral anemia and vasovagal syncope as a consequence.

Hemodilution and tilting responses. On the assumption that reduced circulatory volume is responsible for the abnormal responses to tilting observed in controlled blood loss, then

replenishment of circulatory volume through compensatory hemodilution should be associated with return of tilting responses to normal

Accordingly, a study was made of the relation between successive tilt test results and hemodilution in 7 subjects subsequent to withdrawal of 1000 to 1500 cubic centimeters of blood. The reduction in the hematocrit was used as the index of hemodilution (4).

A return to normal tilting responses required from 24 to 72 hours and was associated with a drop in the average hematocrit value from 47 to 38 per cent (Fig. 5). The apparent therapeutic paradox of a patient who improved as the hematocrit fell was seen in each instance.

Responses to tilting in gastrointestinal hemorrhage. The tilt test was carried out in a group of 11 individuals admitted because of a history of recent gross gastrointestinal hemorrhage but free of obvious evidences of shock at the time of initial observation.

The responses of 3 individuals were within normal limits and no emergency transfusions were given. All recovered uneventfully. One of the 3 received 500 cubic centimeters of blood prior to discharge to accelerate the treatment of a secondary anemia.

Two patients developed reactions similar to the primary response observed following controlled blood loss. One of the 2, a woman aged 48 years, was given 1500 cubic centimeters of blood. A subsequent gastric resection was performed without incident. The

other, an acutely alcoholic male, aged 32 years, developed *delirium tremens* shortly after admission. Because of the likelihood that an abnormal tilting response had been produced by the anesthetic and vasodilator actions of the alcohol, blood was withheld and intensive treatment with intravenous fluids, glucose, insulin and vitamins was substituted. Recovery was uneventful.

The remaining 6 patients manifested secondary reactions with reductions in blood pressure to shock levels. They were given an average of 2000 cubic centimeters of blood. Five recovered satisfactorily. The sixth, whose source of hemorrhage was a ruptured esophageal varix, ultimately died of hepatic failure.

COMMENTS

The standard deviations of the values for the circulatory changes observed in this study (Table II) indicate that significant differences in the responses to tilting were associated only with acute blood loss exceeding 9 cubic centimeters per kilogram.¹

The actual limits of change in pulse rate and blood pressure under the conditions of the test were found to be somewhat narrower both in normal persons and in those suffering from nonhemorrhagic diseases than the ranges which have been reported when similar classes

¹True orthostatic hypotension as a rare but possible cause of abnormal tilting responses may be ruled out by history. Abnormal responses are produced also by morphine (3) and general anesthetic agents (3).

of individuals have been made to stand up (9). This difference may be due to the essentially passive nature of the change in position produced by tilting. In contrast the act of standing is complicated by the necessity for complex voluntary motor activity. The expenditure of muscular energy which the act requires may overtax the limited resources of certain patients. Whatever the explanation the data obtained to date suggest that acute blood loss is manifested more specifically by the response to tilting than by the reaction to standing up.

The variation in ability of normal individuals to compensate for blood loss is compatible with the expected scatter in distribution of responses to any physiological stress. However certain circulatory changes on tilting from 0 to 75 degrees were sufficiently characteristic of definite grades of blood loss for their selection as potentially useful standards.

1 The pulse rate increase on tilting individuals in the normal aged, cardiovascular or anemic groups never exceeded 25 beats per minute. It always exceeded this figure following a blood loss of 1000 cubic centimeters. An increment of 30 beats or more was noted in 10 of 11 subjects in this latter group while only 1 of 19 subjects who had lost 500 cubic centimeters manifested a similar rise.

2 The secondary syncopal reaction was observed in 4 of 5 individuals who lost an average of 1500 cubic centimeters of blood, while it occurred in but 4 of 30 deprived of 500 to 1000 cubic centimeters and in none in whom acute blood loss had been absent.

3 Within the extremes of the range of blood loss explored the manifestations of shock were noted in no subject prior or subsequent to tilting as long as the supine position was maintained.

CONCLUSIONS

From the total of these observations certain tentative guides to therapy seem applicable to the patient who has had a hemorrhage.

1 An increase in cardiac rate less than 25 beats per minute on tilting in the absence of a syncopal reaction indicates either a negligible or a compensated acute blood loss. Transfusion is not required as an emergency therapeutic measure although the degree of anemia or possibility of recurrent bleeding may sug-

gest its desirability as a prophylactic means.

2 An increase in cardiac rate on tilting of 30 beats or more per minute over that observed in the supine position suggests a blood volume deficit of 9 to 14 cubic centimeters per kilogram and a probable transfusion requirement of 1000 cubic centimeters.

3 The occurrence of a syncopal reaction to tilting suggests a probable blood volume deficit of 14 to 20 cubic centimeters per kilogram and the advisability of a transfusion of 1500 cubic centimeters.

4 The presence of shock in patients maintained in the supine position indicates a probable blood volume deficit in excess of 20 cubic centimeters per kilogram and a need for transfusion of 2000 cubic centimeters or more. This figure agrees with the average quantity found to restore blood volume to normal in studies of hemorrhagic shock by the dye method (7).

5 The hematocrit value bears no direct relationship to the magnitude of recent hemorrhage. A falling hematocrit level indicates only that hemodilution is occurring not the continuation or recurrence of hemorrhage.

Due to the normal variation in response to hemorrhage it is estimated that in 15 per cent of patients the transfusion requirements postulated will exceed the minimum needed to prevent further hemodilution and restore the circulatory volume to normal. This occasional excess is considered to represent a reasonable margin of safety for the majority of cases.

CIRCULATORY AND RESPIRATORY DISTRESS FROM EXTREME POSITIONS ON THE OPERATING TABLE

H. C. SLOCUM, M.D., E. A. HOEFLICH, M.D., and C. R. ALLEN, M.D., Ph.D., Galveston, Texas

THE proper position of the patient on the operating table in conjunction with well balanced anesthesia should facilitate the surgical procedure and allow only minimal interference with the physiological processes of respiration, circulation and neurogenic control. In many instances however the position requested is so extreme that few normal conscious individuals can voluntarily assume such for as long as 30 minutes. If the anesthesia is not too profound the majority of anesthetized patients will temporarily adjust themselves to these physiologically poor positions by the utilization of compensatory vasomotor and respiratory changes. Many individuals with systemic disease are unable to make adequate adjustments and within a short time manifest signs of distress by either respiratory or cardiovascular changes or a combination of the two. From the standpoint of the proper functioning of these two systems the supine horizontal position is the one best tolerated by the anesthetized patient.

The studies of Case and Stiles on the effects of surgical positions on vital capacity show that reductions of about 15 per cent occurred in lithotomy, Trendelenburg, kidney and jackknife positions (3). If such a decrease in vital capacity occurs in unnarcotized subjects within 3 minutes after being placed in these positions greater changes in the same direction may occur over longer periods of time. Since vital capacity studies presuppose a conscious subject the test is not directly applicable to anesthetized patients. In our own studies of the effects of different positions upon the tidal volumes of anesthetized patients we have noted changes in the residual air volumes which are in keeping with the changes reported by Case and Stiles for vital

capacity. If the patient with a low vital capacity due to systemic disease is placed in a position which further reduces his respiratory volume serious complications may arise.

In normal breathing the thoracic cage enlarges in all directions except posteriorly. With the deeper planes of anesthesia the intercostal part of respiration tends to be abolished and most of the load of breathing is shifted upon the diaphragm. The excursion of the diaphragm during the expiratory phase is impaired by the loss of abdominal muscle tone. If during such conditions the patient is so placed that he rests upon his lower ribs either in the prone or lateral position respiratory embarrassment will be evidenced by either rapid and shallow breathing or apnea and by secondary circulatory changes. Abnormal shallow breathing has been shown to result in incomplete ventilation which in turn may cause hypoxemia (5). Moreover any factors which cause elevation of the diaphragm such as increased abdominal pressure due to abdominal packs, tight abdominal binders, flat prone or steep Trendelenburg positions predispose to the development of atelectasis during or following the surgical procedure.

Circulatory distress most often begins as the result of venous and capillary stasis in dependent extremities or as the result of the splanchnic pooling of blood. There are four factors which normally aid the venous return in raising the blood against gravity. If any or several of these factors fail the accumulation of blood in the dependent parts is likely to occur.

The first factor of venous return is the impetus given the blood by the contraction of the left ventricle. Myocardial depression may result directly from high concentrations of most any of the anesthetic drugs when used for profound anesthesia. It may also occur as the result of hypoxia accompanying respi-

Fig. 1 Jackknife position without blocks beneath pelvis.

ratory distress or secondary to low arterial pressure.

A second factor is the support of the vein walls due to the tonus of the abdominal and limb muscles. The intermittent contractions of the skeletal muscle fibers which in conjunction with the valves of the veins, propel the blood in the upward direction is decreased and often abolished by anesthetic drugs.

A third factor is the suction and force-pump action on the great veins produced by normal respiratory movements. This function of breathing is reduced by (a) profound anesthesia (b) interference with intercostal activity due to pressure upon the lateral or ventral surface of the thorax and (c) interference with diaphragmatic excursion as the result of increased intra abdominal pressure.

As a fourth factor the vasopressor and capillary tonus mechanisms control the caliber of the venocapillary vessels of the splanchnic area and prevent the venous blood from becoming pooled in this area at the expense of the effective circulatory volume in other regions. Autonomic response to surgical manipulation or to severe pressure occasioned by the acute angulation of the body in the jackknife or kidney position may produce stagnation of blood in the splanchnic area. Low oxygen tensions, high carbon dioxide tensions and various anesthetic agents will dilate capillaries and venules with the same result.

As long as the deeply anesthetized patient is in the supine horizontal position the effects of gravity are annulled but at least three of the four compensatory controls are depressed

Fig. 2 Circulatory distress from acute jackknife position. Case No. 2752.

so that changes from the horizontal position may be fraught with serious complications.

Records showing the harmful effects of improper position are not always clear cut because of the complicating factors of hemorrhage, trauma, obstructed airway, anesthetic overdose, procaine reactions, etc. which in themselves cause marked variations in respiration and circulation. Leveling of the table will usually relieve the distress of malposition more effectively than a blood transfusion.

Figure 1 demonstrates the jackknife position. Here, it is noted that the dependent position of the legs, arms, and head would tend to reduce the venous return to the heart. If to this pull of gravity is added the effects of spinal anesthesia or deep general anesthesia with the accompanying loss of skeletal muscle tonus and sympathetic vasomotor control a venous and capillary stasis would occur. Costal excursion is reduced by pressure on the ventral surface of the thorax. The increased intra abdominal pressure resulting from the ventral compression of the abdomen and the weight of the viscera in the head low position interfere with the respiratory exchange and the pumping action of the diaphragm as an aid in venous return.

The anesthesia record shown as Figure 2 is that of a 58 year old male with a physical

Fig 3. Steep Trendelenburg position.

status of 1. Previous testing had shown the patient not to be hypersensitive to procaine. Eighty milligrams of this drug were injected at the fourth lumbar interspace with the patient in the sitting position so that saddle analgesia for a hemorrhoidectomy would be obtained. Five minutes later the patient was placed in the prone position and 10 minutes later he was flexed to the extreme jackknife. Twenty minutes after assuming the latter position the blood pressure dropped markedly and the skin became cold and clammy. The patient became nauseated and vomited. The level of the analgesia did not rise above 12 dorsal at any time during the course of the operation. The administration of an infusion 25 milligrams of ephedrine intramuscularly and oxygen gave no significant improvement. When the table was raised to the horizontal position there was a prompt return of systolic diastolic and pulse pressures to comparatively normal levels. We have noted similar distress when only local infiltration anesthesia was being used and similar improvement in these cases by leveling the table.

Our recommendations for procedures which are best accomplished with the patient in this position are (a) use small pillows or blocks under the pelvis and upper chest in order to minimize interference with respiratory exchange (b) if general anesthesia is employed avoid the deeper planes (c) flex the table only far enough to allow satisfactory exposure of the operative site.

Steep Trendelenburg position is demonstrated by Figure 3. The diaphragm during

Fig 4. Respiratory distress associated with steep Trendelenburg position. Case No 2939.

the inspiratory phase must lift the weight of the abdominal contents. Profound anesthesia which is accompanied by partial or complete intercostal paralysis therefore would leave an inhibited diaphragm to carry the load of breathing. The decrease of the functional residual air in the Trendelenburg position suggests that changes in intrapleural pressure occur in this position which tend to make respiration more difficult and impair the return of venous blood to the heart (1). In the head down position the cardiac output per minute and per beat is decreased and the arteriovenous oxygen difference increased over the values obtained with the patient horizontal (4).

It is unlikely that the circulation through the brain is increased in patients in the head down position. Venous and cerebrospinal fluid pressures are increased in the brain thus interfering with the inflow of the arterial blood into the rigid confines of the cranial vault. Animal experimentation has shown that this results in an initial slowing of the circulation followed by a return to normal (4).

Obese individuals do not tolerate steep Trendelenburg positions. In Figure 4 the record shows marked respiratory distress

Fig. 5. Kidney or lateral jackknife position.

beginning immediately after the patient was so placed. The depth of anesthesia was varied during the next hour without relief of symptoms. The distress continued until the table was brought back to the horizontal plane.

Our suggestions for this position would be (a) do not use a 30 degree Trendelenburg position if the procedure can be done adequately with one of only 15 degrees (b) do not use this position to compensate for blood loss (c) if the extreme position is indicated limit its use to that part of the surgical procedure which demands it. The reflex abdominal pos-

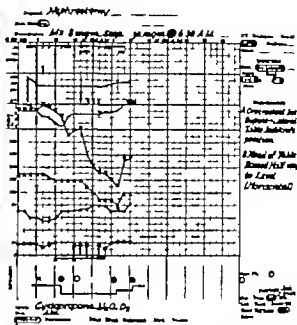

Fig. 6. Circulatory and respiratory distress from kidney position for nephrectomy. Case No. 1745.

ture (6) favors relaxation of the abdominal muscles and may well be chosen for most abdominal operations.

The lateral kidney position is demonstrated in Figure 5. Intercostal breathing is interfered with on the dependent side by pressure on the thorax and on the upper side by increased tension on the lumbar and intercostal muscles. Venous return to the heart from all the extremities is retarded by gravity. Trauma due to this position and to surgical manipulation is transmitted to the splanchnic nerves and related plexuses causing an autonomic imbalance. Figure 6 presents the record of an individual aged 50 physical status 3 who did not compensate satisfactorily for the harmful effects of being placed in this position. When head of table was raised toward the horizontal level an immediate rise in systolic, diastolic and pulse pressures occurred and supplementary breathing was no longer necessary.

Figure 7 is the anesthesia record of a 27 year old patient with a physical status of 1. She was placed in the lateral acute kidney position in order to secure maximum exposure for a nephrolithotomy. Her previous respiratory rate during anesthesia of 20 apparently normal breaths per minute changed to

Fig. 7. Respiratory embarrassment, lateral jackknife position for nephrolithotomy. Case No. 57.

Fig 8. Extreme lithotomy with thighs flat on abdomen

apnea as soon as the patient was laterally flexed. After 5 minutes of passive respiration spontaneous breathing returned at a rate of 44. Fast shallow respiration persisted for the next 30 minutes until the table was raised to the horizontal position. The respiratory rate slowed to 24 and remained thus with good exchange for the duration of the surgical procedure. It was believed that the distress in this case was primarily due to pressure interference with respiratory movements. Nervous factors due to unusual stress in the splanchnic areas and circulatory embarrassment undoubtedly contributed to the condition.

Our suggestions relative to the lateral jack knife or kidney position are (a) avoid extreme flexion of the patient on the table whenever possible (b) confine the use of braces or kidney rest to the crest of the ilium and do not allow pressure against the ribs on the dependent side, (c) avoid the deeper planes of anesthesia (d) employ supplemental breathing to avoid hypoxia if the exchange is poor.

The lithotomy position with extreme flexion of the thighs plus Trendelenburg (Fig 8) is poorly tolerated by the obese patient due to the respiratory impairment resulting from the increased intra abdominal pressure. Figure 9 shows the record of a 239 pound hypertensive female aged 43 when placed in the lithotomy position for a brief gynecological operation. Respiratory distress was marked throughout.

When the legs are lowered following the completion of the perineal portion of a perineoabdominal resection may occur due to the

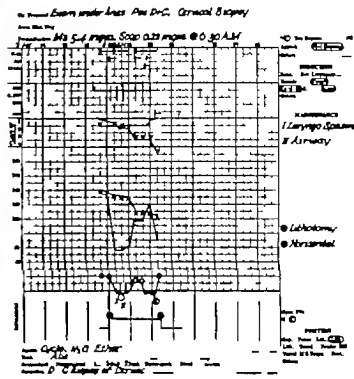

Fig 9. Cardiovascular and respiratory changes of an obese patient in the lithotomy position. Case No. 688

disparity between the increased functional volume of the vascular bed and the volume of circulating blood. Figure 10 shows a marked drop in blood pressure and pulse pressure occasioned by this change of position.

Fig 10. Circulatory distress occasioned by abruptly changing from the lithotomy to the horizontal position. Case No. 2771

Fig. 9 Gall-bladder position with high elevation of the rest.

The high gall bladder rest used with the cholecystectomy position (Fig. 10) necessitates profound anesthesia in order to relax the tension of the stretched abdominal muscles. In dogs we have noted an interference with the venous return from the kidneys and lower extremities due to partial collapse of the inferior vena cava as it is stretched against the hyperextended vertebral column. A similar condition with patients in the extreme gall bladder position appears to be possible. Figure 12 illustrates a circulatory response to the elevation of the gall bladder rest.

Vigorous retraction on the lower ribs plus the trauma occasioned by the relaxation of the back muscles while the rest acts as a fulcrum against the suspended back probably cause as much discomfort and hesitancy to breathe deeply after the operation as does the pain from the actual site of the surgical procedure.

A folded sheet under the lower ribs plus good abdominal relaxation affords sufficient exposure so that this rest is never needed for upper abdominal surgery in our hospital. Block of the anterior divisions of the lower intercostal nerves facilitates abdominal muscle relaxation and allows the maintenance of light surgical anesthesia with good respiratory exchange. A further advantage of an intercostal block is that patients can breathe deeply in the immediate postoperative period without pain. With the use of the opiates thus reduced respiratory depression and atelectasis are minimized.

The prone horizontal position (Fig. 13) is tolerated satisfactorily by patients of average

Fig. 10 Cardiovascular changes associated with elevation of gall-bladder lift. Case No. 862.

build; however the individual with a protruberant abdomen and poor abdominal muscle tone soon shows signs of distress. If an obese individual lies flat on the table, the intra-abdominal pressure will interfere with diaphragmatic action. If the pelvis is elevated with blocks so that the abdomen with weak muscular support swings free the systemic blood pressure often drops abruptly. In some such instances the pulse and pressure have not been detectable until the blocks have been removed and the patient turned back to the supine position. This circulatory failure occurs most frequently when a deeply anesthetized patient is suddenly turned from the supine to the prone position or when the visceral vessels have poor sympathetic tonus such as accompanies the second stage of thoracolumbar sympathectomy. The effective factor appears to be the pooling of blood in the visceral vessels due to inhibited splanchnic tonus and the uphill drainage from these dependent vessels into the overhanging inferior vena cava.

The record shown in Figure 14 is that of an obese female aged 43 scheduled for the second stage of a bilateral thoracolumbar sympathectomy. The patient was given identical dosages of premedication and avertin for basal

Fig. 13. Flat prone position without the advantages of properly placed blocks.

narcosis as she had received for the first stage procedure which was well tolerated. The induction with cyclopropane was uneventful. The patient was turned to the prone position and a pelvic rest elevated until the abdominal wall swung clear of the table. Within 5 minutes the respiration ceased, the pulse and the blood pressure were not obtainable. The operation was postponed. Two days later the patient was again prepared for the surgical procedure but the premedication was less than on the previous occasions and the avertin was omitted. Cyclopropane was used for the anesthetic and the pelvic elevator was not raised. The course of the operation was uneventful. We have learned to respect the decreased tolerance of the patient in the prone position after the splanchnic nerves have been sectioned or depressed.

The sitting position affords the least interference with costal respiration. An abdominal binder is recommended for patients with visceroproposis or relaxed abdominal musculature as these conditions inhibit the excursion of the diaphragm by permitting the viscera to exert an increased downward pull. Since the breathing then is largely costal, deep surgical anesthesia must be avoided. A further contraindication to the use of profound anesthesia is the tendency of the blood to accumulate in the lower extremities and visceral area. The application of elastic bandages to the feet and legs while the patient is still in the supine position is desirable.

In the sitting position even short periods of anoxia resulting from low arterial pressure may damage the cerebral cortex. For this reason personality changes following neuro-

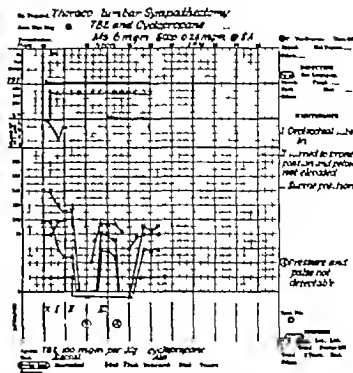

Fig. 14. Vascular collapse and respiratory failure occasioned by a rapid change from the supine to the prone position and high elevation of the pelvic rest. Case No. 2703.

surgical procedures should not always be attributed to the trauma and edema coincident with the operation.

SUMMARY

The supine horizontal position is the one best tolerated by the anesthetized patient. Circulatory embarrassment due to the increased effects of gravity upon venous return are directly proportional to the variation from the horizontal plane. Other causes of circulatory embarrassment are (a) loss of muscle tone (b) loss of autonomic tone (c) abnormal intrathoracic pressure (d) respiratory depression (e) abnormal intra abdominal pressure (f) systemic disease. Respiratory embarrassment occurs with depression of nervous control whether central or peripheral and with mechanical interference with respiratory excursion. With extreme positions of Trendelenburg or lithotomy, the increased abdominal pressure upon the diaphragm may markedly inhibit its activity while lateral or prone positions with improperly placed blocks and pressure interfere with intercostal excursions.

Adequate respiratory exchange should be maintained thereby avoiding the muscle tension accompanying hypoxia. If the anesthetist

produces the degree of relaxation afforded by the anesthetic drugs available, he will find that the surgeon will usually co-operate and not demand extreme variations of position from the horizontal for patients with poor reserve. If respiratory and circulatory depression can be forestalled by avoiding the extremes of position more time may safely be used for the surgical procedure. The patient also will benefit by experiencing a less stormy postoperative course.

THE EFFECT OF MECHANICAL ARTIFICIAL RESPIRATION UPON MAINTENANCE OF THE CIRCULATION

SAMUEL ALCOTT THOMPSON M.D., F.A.C.S. and EDWARD ERNEST ROCKEY M.D.,
New York New York

THE two principal functions of resuscitation are oxygenation of the blood and the circulation of this oxygenated blood to the vital centers. Oxygenation of the blood takes place through pulmonary ventilation. Pulmonary ventilation has long been considered to be the sole requisite of resuscitation and indeed up to the time of circulatory cessation adequate pulmonary ventilation may be all that is necessary for resuscitation to be successful. Once the circulation has stopped however the situation is drastically changed and pulmonary ventilation alone cannot be expected to bring about a successful resuscitation. The oxygenated blood in the lungs is of little or no value unless it can be transported to the vital centers and distributed over the body.

This brings us up to the second function of resuscitation namely the transportation and distribution of the oxygenated blood to the cells of the cardiac and central nervous systems. In past experimental work (2) we gained the clinical impression that the inflation and deflation of the lungs had a very definite effect upon the movement of the blood column in addition to and beyond the effect of the active heart beat.

Not until recently has it been possible to demonstrate whether or not a given resuscitation procedure could produce any actual movement of the blood itself. The purpose of this paper is to describe a method for determining the effect of various resuscitative procedures upon the circulation. Essentially the method consists in the introduction of a tracer substance into the blood stream of an animal immediately following death by asphyxiation and recording any movement of this substance during the application of a resuscitative pro-

cedure. The tracers which have been used are radioactive sodium which we have previously reported (3) fluorescein and oxygen. This report concerns the use of oxygen only.

While pulmonary ventilation has received most of the emphasis in the investigative work of modern authors it remained for the Russians to attack this problem of resuscitation from the viewpoint of circulation rather than ventilation. Negovsky and his co-workers have demonstrated in dramatic fashion the value of circulatory movement by the intravascular injections of oxygenated blood and glucose under positive pressures. While these authors emphasize the transportation or circulation of oxygenated blood nevertheless they call attention to the absolute necessity of adequate pulmonary ventilation being provided at the same time.

The degree and efficiency of pulmonary ventilation varies in each method of resuscitation. All methods produce ventilation by one of three ways (1) inflation of the lungs and return to the starting point (2) deflation of the lungs and return to the starting point (3) a combination of inflation alternating with deflation of the lungs.

The manual methods are inefficient, inconstant and uncontrollable. The mechanical methods are more efficient and are controlled by a constant volume or pressure. Only those resuscitating apparatuses employing a controlled pressure can be safely used.

The use of oxygen as a tracer substance differs from the intravascular injection of other tracers in that oxygen is not injected but is brought into contact with the blood in the pulmonary capillaries by means of a closed ventilating system. In a condition of anoxia, a stream of oxygen directed into the terminal air sacs of the lung will come into contact with the red blood cells. These cells take up the oxygen and are then transported over the

THE EFFECT OF MECHANICAL ARTIFICIAL RESPIRATION UPON MAINTENANCE OF THE CIRCULATION

SAMUEL ALCOTT THOMPSON M D F.A.C.S. and EDWARD ERNEST ROCKEY M D
New York New York

THE two principal functions of resuscitation are oxygenation of the blood and the circulation of this oxygenated blood to the vital centers. Oxygenation of the blood takes place through pulmonary ventilation. Pulmonary ventilation has long been considered to be the sole requisite of resuscitation and indeed up to the time of circulatory cessation adequate pulmonary ventilation may be all that is necessary for resuscitation to be successful. Once the circulation has stopped however, the situation is drastically changed and pulmonary ventilation alone cannot be expected to bring about a successful resuscitation. The oxygenated blood in the lungs is of little or no value unless it can be transported to the vital centers and distributed over the body.

This brings us up to the second function of resuscitation namely the transportation and distribution of the oxygenated blood to the cells of the cardiac and central nervous systems. In past experimental work (2) we gained the clinical impression that the inflation and deflation of the lungs had a very definite effect upon the movement of the blood column in addition to and beyond the effect of the active heart beat.

Not until recently has it been possible to demonstrate whether or not a given resuscitation procedure could produce any actual movement of the blood itself. The purpose of this paper is to describe a method for determining the effect of various resuscitative procedures upon the circulation. Essentially the method consists in the introduction of a tracer substance into the blood stream of an animal immediately following death by asphyxiation and recording any movement of this substance during the application of a resuscitative pro-

cedure. The tracers which have been used are radioactive sodium which we have previously reported (3) fluorescein and oxygen. This report concerns the use of oxygen only.

While pulmonary ventilation has received most of the emphasis in the investigative work of modern authors it remained for the Russians to attack this problem of resuscitation from the viewpoint of circulation rather than ventilation. Negovsky and his co-workers have demonstrated in dramatic fashion the value of circulatory movement by the intravascular injections of oxygenated blood and glucose under positive pressures. While these authors emphasize the transportation or circulation of oxygenated blood nevertheless they call attention to the absolute necessity of adequate pulmonary ventilation being provided at the same time.

The degree and efficiency of pulmonary ventilation varies in each method of resuscitation. All methods produce ventilation by one of three ways (1) inflation of the lungs and return to the starting point, (2) deflation of the lungs and return to the starting point (3) a combination of inflation alternating with deflation of the lungs.

The manual methods are inefficient, inconstant and uncontrollable. The mechanical methods are more efficient and are controlled by a constant volume or pressure. Only those resuscitating apparatuses employing a controlled pressure can be safely used.

The use of oxygen as a tracer substance differs from the intravascular injection of other tracers in that oxygen is not injected but is brought into contact with the blood in the pulmonary capillaries by means of a closed ventilating system. In a condition of anoxia a stream of oxygen directed into the terminal air sacs of the lung will come into contact with the red blood cells. These cells take up the oxygen and are then transported over the

tion of the body may produce a corresponding movement of the blood column ahead of and behind that section where the movement was initiated.

We have been able to demonstrate that the situation described does take place and that the mechanical inflation and deflation of the lungs does produce a movement of the blood column and in this manner the blood can be circulated over the entire body //

TECHNICAL PROCEDURE

All of the experimental procedures were done on dogs. The animal was anesthetized with intraperitoneal nembutal. One femoral artery and one femoral vein was cannulized and the cannula left in site. An endotracheal tube with occlusion cuff was then inserted and the cuff inflated to make a leak proof and closed connection with the lungs. A sample of blood was collected from one of the femoral arteries and femoral veins for determination of its oxygen saturation or tension. The specimens were collected under oil and the oxygen tension was determined by the Van Slyke manometric method. This first specimen was labeled as 'preasphyxia,' and was used for comparison. To prevent the intravascular clotting of the blood which occurs soon after death, 2 to 5 cubic centimeters of heparin was injected intravenously. Five to 10 minutes after the heparin was injected the endotracheal tube was clamped off and the animal was allowed to succumb by obstructive asphyxia. Clinical death took place in about 8 to 10 minutes. In order to insure complete (biological) death with no subsequent cardiac activity the tube remained clamped for an additional 20 to 30 minutes. At the end of this time a second specimen of blood was collected from the femoral artery and vein for analysis of the oxygen tension and this was labeled postasphyxia. The endotracheal tube was now unclamped and connected to a resuscitator. A resuscitative procedure was begun and continued for 45 to 60 minutes. At approximately 5 minute intervals additional specimens of blood were taken from the femoral artery and vein for analysis of the oxygen tension.

This method of frequent analysis of the blood in the femoral vessels made it possible to determine any change in the oxygen tension while the lungs were being mechanically inflated and deflated with oxygen. If this in-

flation and deflation of the lungs produces a forwarding movement of the oxygenated blood cells in the pulmonary capillaries there would be a gradual increase in the oxygen tension of the blood in the femoral vessels since the blood in the pulmonary capillaries is now thoroughly oxygenated. A total of 15 experiments were done. Alternating positive and negative pressures were used in 5 experiments positive pressure and release was used 4 times and negative pressure (suction and release) was used 6 times. From each group 3 typical experiments were charted.

The resuscitators delivered a positive pressure of 14 millimeters of mercury and a negative pressure of minus 9 millimeters of mercury. A separate resuscitator was used for the positive pressure and the negative pressure and the alternating positive and negative pressures. The resuscitators for the alternating pressures and for the positive pressure delivered 100 per cent oxygen. The resuscitator for the negative pressure used a mixture of equal parts of atmospheric air and 100 per cent oxygen. This would make the oxygen content of the gas delivered by the negative pressure resuscitator only 60 per cent. The rate of the inflation and deflation of the lungs was approximately 20 per minute.

DISCUSSION

The only place where blood cells can become oxygenated is in the pulmonary capillaries and the only way these oxygenated cells can be transported is through the vascular system. The gradual appearance and increase, after asphyxia of oxygenated cells in the femoral artery constitutes definite proof of the forwarding movement of the blood from the pulmonary capillaries to the femoral artery. As the heart is no longer beating or active this forwarding movement of the blood is produced by the mechanical inflation and deflation of the lungs. Therefore in mechanical artificial respiration we have a method of producing pulmonary ventilation as well as circulation of the blood.

The type of resuscitation seems to make a considerable difference in the pulmonary ventilation and also in the speed of the circulation. A study of the tables and charts shows that

when alternating positive and negative pressures are used the oxygen tension of the blood in the femoral artery regains its preasphyxia level in approximately 17 minutes and the blood as it is withdrawn from the femoral artery changed in color from a dark blue (black) to a bright red color in approximately 14 minutes. This visual color test varies from time to time and is subject to criticism because of its lack of complete accuracy however we believe it does have some value.

When the positive pressure resuscitator was used the oxygen tension of the blood in the femoral artery regained its preasphyxia level in approximately 31 minutes, and the blood was visibly bright red in approximately 25 minutes. Both of these times are considerably longer than when alternating positive and negative pressure resuscitation was used.

When the negative pressure resuscitator was used the oxygen tension of the blood in the femoral artery regained its preasphyxia level in approximately 35 minutes and the blood became visibly bright red in 23 minutes. This also is longer than the results obtained when the alternating pressure resuscitator was used. There is little difference in the comparison of the results obtained by the use of the positive pressure resuscitator and the negative pressure although the latter machine delivered only 60 per cent of oxygen therefore these figures would be subject to an upward revision if 100 per cent oxygen had been delivered. Both are inferior to the alternating pressure resuscitator.

It will be noted that the oxygen tension of the blood in the femoral vein in no instance regained its preasphyxia level and on the contrary the longer the resuscitation the lower the oxygen tension of the venous blood. The only explanation we can offer for this is that the blood column was moving so slowly that in the passage through the tissue capillaries the oxygen was more or less completely removed and utilized by the anoxic tissues.

The movement of the blood column by the mechanical inflation and deflation of the lungs

is in no way comparable to the volume or speed of the normal circulation. However the fact that such movement of the blood can be produced seems to be of definite clinical importance.

In a previous report (3) we called attention to the value of heparin in resuscitation. This prevents clotting and keeps the blood in a fluid state. As a result the blood can be more effectively circulated and this increases the possible survival time. Once the blood is clotted there is no possibility of any further circulatory movement.

CONCLUSIONS

We have described a method for determining the effect of mechanical artificial respiration upon the circulation when the heart is no longer beating. This is done by the introduction of tracer substances into the vascular system of animals immediately after death, and observing the movement of these tracers while the lungs are inflated and deflated. The tracer which was used in this series of experiments was oxygen.

By this method we have shown that the mechanical inflation and deflation of the lungs produces an actual movement of the blood column and that the blood can be circulated over the entire body without the benefit of any heart action whatever.

Mention is again made of the value of heparin in resuscitation.

Those mechanical resuscitators employing positive and negative pressures were more efficient in circulating the blood than were those employing only positive pressure and release or negative pressure and release.

A STUDY OF PROTEIN HYDROLYSATES, OSSEIN GELATIN AND GLUCOSE IN PARENTERAL NUTRITION

C. E. KOOP M.D. CECILIA RIEGEL, Ph.D. ROZANNE P. GRIGGER, A.B. and
M. T. BARNES Philadelphia, Pennsylvania

In the belief that the maintenance of nitrogen equilibrium would reduce the period required for convalescence in surgical patients an intensive study of a number of available products for parenteral nutrition was undertaken. The usefulness of parenteral feeding is confined to those patients in whom oral feeding cannot be accomplished safely. Such patients are usually those with lesions of the gastrointestinal tract as peptic ulcer or neoplasm in esophagus, stomach or intestine.

We were concerned on the one hand with the effectiveness of the various feeding programs in producing a positive nitrogen balance and on the other hand with the various practical difficulties such as thrombosis, pyrexia or nausea which tend to interfere with the success of the method.

Among the objectives of the study were the following: (1) to determine what the nitrogen and caloric requirements for equilibrium would be after major operations; (2) to determine whether they would be substantially different from the amounts required enterally; (3) to determine whether there were any striking differences in the response of patients to the different preparations of hydrolyzed protein tested; (4) to determine the value of ossein gelatin as a constituent of a nutritive mixture for intravenous administration.

Inasmuch as the studies were carried out in patients, there were too many uncontrolled variables to permit the detection of small differences.

METHODS

The collection of specimens and the analytical methods were the same as those reported

in an earlier paper (6). The intravenous infusions were given continuously when possible and it was seldom that any patient received his infusion less than 22 hours per day. Thus the rate of infusion could be reduced to about 125 cubic centimeters per hour. In every instance the administration was carried out by a closed system and, in general, the infusion was not allowed to run into the same vein for more than 24 hours. The period of study was 5 days beginning within 24 hours after operation unless otherwise indicated.

The preparations used were as follows:

1. Paranamine (15 per cent solution) an acid hydrolysate of casein fortified by the addition of tryptophane.
2. Amigen (5 per cent with 5 per cent glucose) an enzymatic hydrolysate of casein and pork pancreas.
3. A similar hydrolysate from which certain substances had been removed by extraction with acetone sent to us in powder form by Doctor Olaf Rask of Johns Hopkins School of Public Health and made up by us in sterile solution of the desired concentration.
4. Casein aminosol (5 per cent with 5 per cent glucose) enzymatic hydrolysate of casein and pancreas.
5. Fibrin aminosol (5 per cent with 5 per cent glucose) an enzymatic hydrolysate of fibrin.
6. Gelatin Knox P 20 6 per cent.

A volume of one or more of these solutions containing sufficient nitrogen to give the patient 0.3 gram of nitrogen per kilogram daily was used as the starting point for the feeding mixture.

An average figure of several analyses was used to calculate nitrogen content of each of the various preparations.

Sufficient amounts of sterile 50 per cent solution of glucose were added to give a caloric intake of 30 calories per kilogram daily and

The work described in this paper was done under contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Pennsylvania.

the total daily volume was made up to 3 000 cubic centimeters. The salt content was varied in accordance with the needs of the patient and additional fluid was given when necessary to compensate for abnormal losses.

The gelatin appearing unchanged in the urine during the period of the infusion was determined and included in the total nitrogen loss. Also the gelatin nitrogen occurring in the urine during the 3 days after the infusion ended was added to the total nitrogen excretion for the period of infusion. The excretion of gelatin after this 3 day period was so small that it could not be determined accurately by the method used (5 6)

RESULTS

The metabolic data obtained are presented in Table I. A nitrogen balance of ± 1.0 gram per day was considered as equilibrium, and figures outside of this range were classified as positive or negative as the case might be. The first 22 patients were fresh postoperative cases. The last 4 were nonoperative patients or were studied before operation.

Three patients who received gelatin as the sole source of nitrogen in amounts ranging from 0.25 to 0.29 gram of nitrogen per kilogram per day remained in negative nitrogen balance. Only 1 of them however received a reasonably good caloric intake (28 calories per kilogram per day). It was to be expected that this incomplete protein would fail to produce nitrogen equilibrium. In fact larger negative nitrogen balances had been expected, and the results suggested the possibility of partial utilization during the 5 day trials.

Twelve patients received 4 preparations of hydrolyzed protein. Eight of these received from 0.26 to 0.31 gram of nitrogen per kilogram per day. One was in equilibrium, and 7 were in negative nitrogen balance. One additional patient who received only 0.20 gram of nitrogen per kilogram per day was in equilibrium. In 3 instances the nitrogen intake was increased to 0.54, 0.62 and 0.69 gram of nitrogen per kilogram per day respectively and all were in strongly positive nitrogen balance.

Seven patients received half the nitrogen intake in the form of gelatin and half in the form of hydrolyzed protein. Five of these re-

ceived 0.30 gram of nitrogen per kilogram per day or less, and in this group 3 were negative and 2 were in equilibrium. One of the 3 who was negative had a very deficient caloric intake. The other 2 patients in this group received 0.40 and 0.47 gram of nitrogen per kilogram per day, and both were strongly positive although their caloric intakes were low. In view of the fact that gelatin is deficient in certain of the essential amino acids it is surprising that the substitution of this material for one half of the protein hydrolysate was followed by comparable results.

Finally 4 nonoperative patients were studied. Nitrogen intake ranged from 0.30 to 0.49 gram per kilogram per day. All were in positive nitrogen balance in spite of the fact that 2 of them had relatively low caloric intakes.

UNTOWARD REACTIONS

Apart from hyperpyrexia two types of reactions were encountered with the intravenous administration of protein hydrolysates, a systemic reaction and phlebitis. The systemic reaction was usually associated with rapid administration of one of the hydrolysates. It consisted of a sensation of flushing over the neck and face accompanied by a sense of constriction about the nose, upper lip and temples. Nausea and vomiting sometimes followed if the infusion was continued at a rapid rate. A number of patients in addition to those having nitrogen balance studies, were tested for the systemic reaction with various hydrolysates. The addition of 1 per cent or more of gelatin protein usually prevented the systemic reaction.

Thrombophlebitis occurred with considerable regularity in the vein employed for the infusion after a number of hours of continuous administration. It sometimes involved tributary veins as well. It was not influenced by the addition of gelatin nor were any of the preparations of hydrolyzed protein free from the tendency to produce it. The use of a plastic tube instead of a needle considerably delayed the onset of thrombosis.

The problem of thrombophlebitis is a serious one because patients who need the benefit of parenteral protein are frequently those who will also need their veins for other infusions.

over long periods. The occurrence of thrombophlebitis following infusion with a casein hydrolysate is mentioned in some of the early papers concerned with its intravenous use, but most of the later reports on this subject fail to mention its occurrence. Thrombophlebitis appeared so important in this study that

biopsies were taken of several veins after infusion to observe the character of the reaction.

The extent of the thrombophlebitis seen 3 days after infusion is shown in Figure 1 while Figure 2 illustrates an organizing thrombus 9 days after infusion. These infusions lasted 48 and 17 hours respectively. Many thromboses

Fig. E. Text of thrombophlebitis seen 3 days after infusion

Fig. A. Organizing thrombus present 9 days after infusion

were seen following infusions of shorter duration. The individual tendency to thrombophlebitis seemed to be a more important factor than the degree of hypertonicity of the solution in determining how soon thrombophlebitis would occur. To cite extreme cases thrombosis occurred with 5 per cent glucose solutions in a few hours in a susceptible individual whereas another individual tolerated a 14 per cent solution of glucose hydrolyzed protein and gelatin for over 4 days without changing the infusion site.

DISCUSSION

It appears from these data, as from the data of others, that positive nitrogen balance is obtainable by parenteral means alone even in the early postoperative period after extensive abdominal procedures. Comparison of the figures in Tables I and II does not indicate that hydrolyzed protein and glucose introduced by vein are any more efficient in bringing about nitrogen equilibrium than when they are given by mouth. In fact, it seemed to be a little more difficult to achieve equilibrium by the parenteral route with these materials.

It should be noted that not all patients can tolerate the intravenous infusion of 6 per cent gelatin solution in the amounts used here. Gelatin is a macromolecular colloid and increases plasma volume to a marked degree (4). When large amounts are used there is danger of producing pulmonary edema and in patients with poor cardiac reserve even small quantities may be harmful. In patients without circulatory symptoms however no difficulty was encountered in giving 0.15 gram of nitrogen per kilogram per day of gelatin nitrogen (about 1,000 c.c. of 6 per cent solution in 24 hours). The suggestion that gelatin might be utilized in the presence of the constituents of a complete protein was made by Brunschwig (1). The fact that the mixture of gelatin and hydrolyzed protein gave slightly better results than when all of the nitrogen was in the form of the derivatives of the complete protein is more surprising when one considers that about one-third of the gelatin was recovered unchanged in the urine. The amino nitrogen appearing in the urine, as determined in 5 patients with an intake of approximately 0.3 gram of nitrogen per kilogram per day, amounted

to only 7 per cent of the total nitrogen given in the 5 day period. This is somewhat greater than the amount of amino nitrogen found in the urine (4 per cent) of patients fed enterally at the same intake level. Elman, Charnas and Davey have reported relatively low figures for amino nitrogen after infusion of hydrolyzed casein in experimental animals.

When the nitrogen intake was increased to 0.40 gram of nitrogen per kilogram per day by the parenteral route, positive nitrogen balance resulted for the 5 day period of study even when the caloric intake was low. This confirms at least for the 5 day period the findings of Elman (3).

The serum protein figures in the patients who received gelatin were low after infusion reflecting the presence of the unnatural macromolecular colloid in the circulation. As the gelatin disappears from the circulation the serum protein concentrations rise toward their former levels (5).

One lot of hydrolyzed protein had a very marked tendency to produce nausea and vomiting in each patient who received it. After the addition of gelatin it was given to many of the same patients without causing this reaction.

With later commercial preparations such reactions were not troublesome, however, nor were pyrogenic reactions frequent. Occasionally after prolonged administration fever still occurs. The susceptibility of these nutrient solutions to contamination is very great. Even the so called closed systems are not entirely safe.

In our experience, however, the most frequent complication of the continuous intravenous infusion of nutrient mixtures in amounts sufficient to meet fully the nitrogen and caloric requirements of the postoperative patient is thrombosis. At present this appears to be the limiting factor preventing the extension of the method to a number of other problems such as that of producing a preoperative weight gain in individuals with pyloric obstruction.

Although some patients develop thrombosis even with isotonic solutions, in general it may be said that the more hypertonic the solution the greater the tendency to thrombosis. From

*From T. B. I. Ref. 6

this standpoint the substitution of large molecular material such as gelatin for part of the small molecular material which constitutes the protein hydrolysates used for intravenous feedings is a step in the right direction.

SUMMARY AND CONCLUSIONS

Nitrogen balance studies were completed in 26 patients for 5 day periods during which food was provided parenterally by means of continuous intravenous infusions of solutions of glucose and various preparations of hydrolyzed protein. Gelatin produced for intravenous use was added in some instances to replace one half of the hydrolysate and in 3 instances it was used as the sole source of nitrogen.

Protein hydrolysates parenterally were no more efficient in producing nitrogen balance than were the enteral methods previously studied. In fact the results were a little less satisfactory.

When gelatin was infused as the sole source of protein in 3 patients positive nitrogen balance was not obtained. However when approximately one half of the protein hydrolysate was replaced by gelatin the results were slightly better than when all of the nitrogen was provided in the form of the hydrolysate.

Nitrogen intakes as high as 0.69 gram of nitrogen per kilogram per day were success-

were seen following infusions of shorter duration. The individual tendency to thrombophlebitis seemed to be a more important factor than the degree of hypertonicity of the solution in determining how soon thrombophlebitis would occur. To cite extreme cases thrombosis occurred with 5 per cent glucose solutions in a few hours in a susceptible individual whereas another individual tolerated a 14 per cent solution of glucose hydrolyzed protein and gelatin for over 4 days without changing the infusion site.

DISCUSSION

It appears from these data as from the data of others that positive nitrogen balance is obtainable by parenteral means alone even in the early postoperative period after extensive abdominal procedures. Comparison of the figures in Tables I and II does not indicate that hydrolyzed protein and glucose introduced by vein are any more efficient in bringing about nitrogen equilibrium than when they are given by mouth. In fact it seemed to be a little more difficult to achieve equilibrium by the parenteral route with these materials.

It should be noted that not all patients can tolerate the intravenous infusion of 6 per cent gelatin solution in the amounts used here. Gelatin is a macromolecular colloid and increases plasma volume to a marked degree (4). When large amounts are used there is danger of producing pulmonary edema and in patients with poor cardiac reserve even small quantities may be harmful. In patients without circulatory symptoms however no difficulty was encountered in giving 0.15 gram of nitrogen per kilogram per day of gelatin nitrogen (about 1000 c.c. of 6 per cent solution in 24 hours). The suggestion that gelatin might be utilized in the presence of the constituents of a complete protein was made by Brunschwig (1). The fact that the mixture of gelatin and hydrolyzed protein gave slightly better results than when all of the nitrogen was in the form of the derivatives of the complete protein is more surprising when one considers that about one third of the gelatin was recovered unchanged in the urine. The amino nitrogen appearing in the urine as determined in 5 patients with an intake of approximately 0.3 gram of nitrogen per kilogram per day amounted

ASPIRATION BIOPSY OF LYMPH NODES

A Critical Review of the Results of 300 Aspirations

R. E. MEATHERINGHAM M D and LAUREN V ACKERMAN M D Columbia Missouri

THERE is a wide divergence of opinion regarding the diagnostic value of the aspiration biopsy (the withdrawal of tissue through a needle by suction), these attitudes ranging from absolute rejection to evangelistic overenthusiasm and over application.

Although the modern use of aspiration technique dates to 1930 at the time when Martin and Ellis (8) reported a simple method used by them at the Memorial Hospital in New York, only a few actual statistical results have been published. It is our purpose to evaluate the aspiration biopsy of lymph node enlargements as a diagnostic aid.

The material presented by these authors has been compiled from 300 consecutive biopsies of lymph nodes (245 patients May 1942 to October 1945) seen at our hospital, an institution limited to the diagnosis and treatment of neoplastic diseases.

The hollow needle puncture for securing tissue for microscopic examination is not a new procedure. Grieg and Gray in 1904 aspirated material from lymph nodes to study the etiology of trypanosomiasis but apparently not until 1915 was this method used to secure the cellular material occurring in lymphoblastomas (14). Goeller (1920) applied the principle to the use of a special trocar for securing prostatic material. Guthrie in 1921 reported observations on material collected by needle puncture and aspiration of lymph nodes in cases of Hodgkin's disease and Forkner (1927) reported in considerable detail the structure of cells that are found in lymph nodes both normal and pathologic, on both fixed and supravital stained material which was obtained by passing a tiny barbed dental broach through a small gauge needle which was inserted into the node.

From the Department of Pathology The Ellis Fischel State Cancer Hospital.

PROCEDURE

The technique of securing aspirated material is essentially that described by Martin and Ellis (8, 9).

Materials required for the procedure are (1) glass piston syringe (20 to 50 c.c.) (2) long (10 cm. or longer) aspiration needle (No. 17 to No. 15) with obturator (3) Bard Parker bistoury (No. 11 stab) blade (4) novocain 1 per cent and 2 cubic centimeter syringe with No. 25 hypo needle (5) surgical lubricant (6) skin disinfectant (7) filter paper fixative. The area to be aspirated is located and the overlying or adjacent skin infiltrated with novocain solution. The node is held steady by the disengaged hand until the procedure is completed. A skin nick is made with the bistoury blade to facilitate insertion of the needle and to prevent contamination of the specimen by bits of surface epithelium. The aspirating needle with the obturator inserted is then thrust through the skin nick and the node engaged with its tip. The obturator is carefully withdrawn and the syringe (with its piston coated with surgical lubricant) is attached to the shank of the needle. Strong negative pressure is then maintained by partial withdrawal of the piston and the needle advanced slowly into the mass with a rotary back and forth motion. The needle is withdrawn to the edge of the mass and again inserted into it several times in slightly different directions. Negative pressure is then slowly released, the syringe disengaged and the needle withdrawn. (If negative pressure is not released the aspirated material may be spattered over the interior of the syringe and some be lost.)

The obturator is now inserted and the core of material within the needle is pushed out upon a small (2 cm.) square of absorbent paper which is then placed in Zenker's solution with glacial acetic acid. *Negligence in following the details of this procedure results in failure.*

fully given for 5 day periods. When the nitrogen intake was 0.40 and 0.47 gram of nitrogen per kilogram per day positive nitrogen balance was observed in 2 patients who were in negative caloric balance (10 and 12 calories per kilogram per day respectively).

Untoward reactions were studied not only in these patients, but in other patients receiving protein hydrolysates in the surgical wards. Hyperpyrexia, local venous thrombosis and a characteristic symptom complex culminating in nausea and vomiting were observed. The addition of gelatin was of value in preventing the symptom complex culminating in nausea and vomiting. However, most of the more recently prepared material (1945) gave little trouble from this standpoint or from the standpoint of hyperpyrexia unless thrombosis appeared. All of the preparations when used for considerable periods resulted in thrombosis.

This could not be entirely prevented by daily change of the infusion site but was delayed by the use of a plastic tube in place of a needle. The tendency was subject to marked variation between individual patients and in several patients the infusion of hydrolyzed protein had to be stopped for this reason. Venous thrombosis appeared to be the chief limiting factor in parenteral nutrition.

ASPIRATION BIOPSY OF LYMPH NODES

A Critical Review of the Results of 300 Aspirations

R. E. MEATHERINGHAM M.D. and LAUREN V. ACKERMAN M.D. Columbia, Missouri

THERE is a wide divergence of opinion regarding the diagnostic value of the aspiration biopsy (the withdrawal of tissue through a needle by suction) these attitudes ranging from absolute rejection to evangelistic overenthusiasm and over application

Although the modern use of aspiration technique dates to 1930 at the time when Martin and Ellis (8) reported a simple method used by them at the Memorial Hospital in New York only a few actual statistical results have been published. It is our purpose to evaluate the aspiration biopsy of lymph node enlargements as a diagnostic aid

The material presented by these authors has been compiled from 300 consecutive biopsies of lymph nodes (245 patients May 1942 to October 1945) seen at our hospital an institution limited to the diagnosis and treatment of neoplastic diseases

The hollow needle puncture for securing tissue for microscopic examination is not a new procedure. Grieg and Gray in 1904 aspirated material from lymph nodes to study the etiology of trypanosomiasis but apparently not until 1915 was this method used to secure the cellular material occurring in lymphoblastomas (14) Goeller (1920) applied the principle to the use of a special trocar for securing prostatic material Guthrie in 1921 reported observations on material collected by needle puncture and aspiration of lymph nodes in cases of Hodgkin's disease and Forkner (1927) reported in considerable detail the structure of cells that are found in lymph nodes both normal and pathologic, on both fixed and supravital stained material which was obtained by passing a tiny barbed dental broach through a small gauge needle which was inserted into the node

From the Department of Pathology The Ellis Fischel State Cancer Hospital.

PROCEDURE

The technique of securing aspirated material is essentially that described by Martin and Ellis (8, 9)

Materials required for the procedure are (1) glass piston syringe (20 to 50 c.c.) (2) long (10 cm. or longer) aspiration needle (No. 17 to No. 15) with obturator (3) Bard Parker bistoury (No. 11 stab) blade (4) novocain 1 per cent and 2 cubic centimeter syringe with No. 25 hypo needle (5) surgical lubricant (6) skin disinfectant (7) filter paper fixative The area to be aspirated is located and the overlying or adjacent skin infiltrated with novocain solution The node is held steady by the disengaged hand until the procedure is completed A skin nick is made with the bistoury blade to facilitate insertion of the needle and to prevent contamination of the specimen by bits of surface epithelium The aspirating needle with the obturator inserted is then thrust through the skin nick and the node engaged with its tip The obturator is carefully withdrawn and the syringe (with its piston coated with surgical lubricant) is attached to the shank of the needle Strong negative pressure is then maintained by partial withdrawal of the piston and the needle advanced slowly into the mass with a rotary back and forth motion The needle is withdrawn to the edge of the mass and again inserted into it several times in slightly different directions Negative pressure is then slowly released the syringe disengaged and the needle withdrawn (If negative pressure is not released the aspirated material may be spattered over the interior of the syringe and some be lost.)

The obturator is now inserted and the core of material within the needle is pushed out upon a small (2 cm.) square of absorbent paper which is then placed in Zenker's solution with glacial acetic acid *Negligence in following the details of this procedure results in failure*

Fig 1. Aspiration biopsy from supraclavicular lymph node involved by epidermoid carcinoma. N 1 large masses of tumor cells.

From this point on the specimen is handled exactly as is other tissue in so far as fixing, clearing, embedding and staining are concerned. Special stains can be made if necessary. Three slides should be made from each specimen and 6 to 8 sections from each of 3 levels should be placed on each slide. Smears of aspirated material are not done in this laboratory for the reason that in our opinion they cannot give the sufficient additional information which the paraffin sections supply. These smears distort the architecture and the diagnosis then must depend on the identification of individual cells.

The most satisfactory material aspirated consists of a plug of tissue of varying length but this is usually dependent upon the nature and consistency of the aspirated mass (Fig 1). Pseudocaseous or keratinoid material may be

obtained from nodes containing epidermoid carcinoma. Bits of soft gelatinous material may be secured from mucinous carcinomas, and in some cases blood may be removed and the bits of tissue be contained in a blood clot. If a great deal of blood is secured it may be placed in 2.5 per cent sodium citrate solution, shaken vigorously, and sections made of the centrifuged sediment. Fat is often secured, and in the region of the salivary glands, characteristic glandular tissue may be obtained. In successful cases the histologic characteristics as well as the cytologic relations are maintained the specimen differing essentially only in size from formal biopsy material.

ADVANTAGES AND INDICATIONS

The necessity for biopsy and histologic diagnosis in the study and treatment of neoplastic diseases is unquestioned (6, 7) and it is equally true that under certain circumstances the aspiration biopsy has certain advantages over other methods of securing material (11, 12, 13). The procedure may safely be employed in an out patient clinic, thus reducing or avoiding hospitalization and the diagnosis may be obtained within 24 hours. Risk of infection is minimized. We have seen no case in which fungation from the needle puncture has occurred. Certainly when lymph nodes are aspirated this danger is more theoretic than actual for if tumor is found therapy can be instituted at once. The capsular defect left after needle puncture is inconspicuous compared to the

Fig 3. Aspiration biopsy from axillary lymph node showing metastatic adenocarcinoma. Primary tumor arose in the breast.

Fig. Aspiration biopsy from cervical lymph node revealing well differentiated epidermoid carcinoma. Not epithelial pearls. Primary tumor arose in the larynx.

large defect resulting from the usual incisional biopsy. No special training is required for securing or preparing specimens. (However, the experience and skill of the operator is reflected in the percentage success of his biopsies.) Evaluation of cure rates may also be facilitated in follow up of treated patients. Operability or inoperability of a lesion may be determined by the presence of distant or regional node metastases. Histologic proof of the presence of a malignant tumor can be established for record purposes in clinically obvious cases. As in any other diagnostic methods, only positive results are conclusive. The aspiration should be repeated without hesitation if it is found to be necessary, formal biopsy may be required but little time is lost in either case.

The indications for aspiration biopsy of enlarged lymph nodes have been considerably extended lacking valid contraindications and augmented by favorable experience in its accuracy and reliability. In general, any enlarged firm node which does not present an overlying ulcerated surface may be investigated by needle puncture and aspiration especially if it is not easily accessible to surgical excision.

Martin and Morfit (10) felt that any lymph node enlargement (except cervical) in adults exceeding 1 centimeter was presumptive evidence of abnormality. But the location of the node, its consistency and the site and histologic character of possible primary tumor are

Fig. 4. Aspiration biopsy from supraclavicular lymph node. Metastatic adenocarcinoma. Primary tumor arose in the stomach.

factors which should have a bearing on whether or not a node is investigated. Obviously the method finds greatest usefulness in tumor clinics for investigation of lymphadenopathy coexisting with a primary lesion or for evaluation of nodes after treatment of a primary lesion.

In patients who exhibit peripheral lymph node enlargement as a presenting symptom, the nature of a possible primary lesion may be determined by microscopic examination of material aspirated from the adenopathy. Of the 3,896 cases reported by Martin and Morfit of patients having a cervical adenopathy as the only presenting symptom, 218 (0.06 per cent) indicated the existence of a silent primary neoplasm as shown by aspiration bi-

opsy of the enlarged nodes. Absolute histologic proof of cancer in large regional nodes draining a foul infected lesion may indicate a radical course of treatment. Conversely proof of a merely inflammatory enlargement of palpable nodes may prevent the performance of a radical procedure.

The one real disadvantage of aspiration biopsy as applied to peripheral lymph node enlargement is that only a small amount of tissue can be secured and consequently it may be impossible to identify the details of capsular invasion and gross structural fine points. In such cases which usually include Hodgkin's disease, lymphosarcoma, etc., an entire node should be taken for study by the usual routine technique.

Primary lymph node disease is best diagnosed by incisional biopsy in which such details as capsular invasion, architectural pattern and reaction of perinodal tissues can be studied carefully. Hyperplastic and neoplastic diseases constitute the bulk of primary diseases of lymphoid tissue if by the term 'neoplastic' we include Hodgkin's disease, follicular lymphoblastoma, lymphosarcoma, and lymphatic leucemia. We are of the opinion that in lymph nodes the presence of other than lymphoid tissue is evidence of a secondary or a metastatic disease.

Recognition of metastatic lymph node enlargement is of the utmost importance in the choice of treatment. We believe that here aspiration biopsy offers the greatest degree of usefulness. It is self-evident that a broad

knowledge of the clinical nature of malignant disease and its mode of spread is a primary requirement. The identification of metastatic lymph node involvement is not always possible, but the usual diagnostic cytologic and histologic criteria are just as applicable for metastatic disease as they are for primary neoplasms. The existence and the nature of a hidden primary lesion may be suggested by the pathologic changes within the lymph node and by its location in some particular lymph node area (Figs. 2, 3, 4, 5 and 6).

RESULTS

Although this is a statistical review the implications are clinical so the results shall be discussed largely from this standpoint. In our study the most common areas of lymph node metastases were in the cervical, submaxillary, axillary, inguinal and supraclavicular areas. The sites of origin for these metastases were for the most part expected but in a few instances a primary carcinoma behaved in a rather unpredictable manner. In the cervical region the most common site of origin was from within the oral cavity in the submaxillary area, from the lower lip and tongue and in the axilla, from the breast. In the supraclavicular area 14 out of 24 originated in the breast. In the inguinal region neoplasms of rectum, anus, cervix, vulva and penis were responsible. Of these 5 large groups of nodes, the greatest percentage accuracy occurred in the supraclavicular group. The reasons for this are apparent considering the infrequency with which that node group is affected by disease other than metastatic carcinoma. The accessibility of the supraclavicular region also leads to a larger percentage of successful biopsies.

The present study is based upon 300 aspirations performed on 245 patients who presented lymphadenopathy considered to suggest the existence of neoplasm. Diagnoses were originally made from all microscopic slides, the slides were recently reviewed the diagnoses checked by one of us (L.V.A.) and review was also made of the subsequent clinical course of the patients and of further procedures which might affect the accuracy of previous diagnoses. In 7 cases originally reported negative

re-examination reversed the diagnosis to positive. In no case were a few questionable cells reported as tumor and in no case was a false positive reported. In this limited series clinical judgment of lymph node involvement in malignant disease was approximately 64.7 per cent correct, as verified by positive biopsies. The figure would undoubtedly be higher if it were not for the fact that all suggestive adenopathies were routinely investigated they were not necessarily considered malignant. Five aspirations revealed primary lymphomas later verified by conventional biopsy. Of these the cervical region was the site of involvement in 3 cases, submaxillary in 1 and axillary in 1. Lymphosarcoma was diagnosed 4 times (Fig 7) and Hodgkin's disease once. Tuberculosis was diagnosed in 4 instances and was proved either by means of animal inoculation or acid fast stain.

One hundred and ninety-seven of the 300 aspirations were considered successful in that either tumor or lymphoid tissue was seen. One hundred and three cases represented technical failure to obtain sufficient tissue but subsequent clinical course or further diagnostic procedures proved only 34 of these to be in error (11.1 per cent of total aspirations.)

Forty two cases were diagnosed as 'lymphoid tissue' and only 5 of these were proved subsequently to be incorrect, placing them in the 'wrong' classification (a technical error of 11.9 per cent). It is thus apparent that a node may contain tumor in another portion or more commonly material from an adjacent uninvolved node may be aspirated and thus normal appearing lymphoid tissue be obtained. But if tissue sufficient for diagnosis is secured our series indicates that one may assume (within 11.9 per cent error) that the diagnosis is correct. The 69 cases in which 'no lymphoid tissue' was reported represent technical failure to obtain lymph node material by means of aspiration, but not failure of diagnosis for they represent cases in which subsequent follow up proved no malignant condition to have been present.

SUMMARY AND CONCLUSIONS

Aspiration biopsy in our experience provides a reliable safe rapid and economical method of investigating lymph node enlargements the accuracy of which within limits of application, very creditably approaches that of other similar diagnostic procedures. The greatest value of the method lies in the evaluation of nodes suspected of being the site of metastatic disease particularly those regional nodes approximating foul and infected primary lesions. The diagnosis of lymphomas was invariably suggested but exact classification could not consistently be made.

The relative merit and indications of incisional or formal biopsy are adjunctive rather than competitive. The decision as to operability or inoperability or the choice of treatment is facilitated by the establishment of the presence or almost certain absence of metastases in enlarged nodes.

Aspiration biopsy also provides an accurate method of determining the presence of metastasis in patients to be treated by roentgen therapy and the size of the field may be chosen accordingly. Empirical treatment based on clinical judgment alone can be avoided, as well as the delay in treatment occasioned by waiting for an incision to heal.

It should be emphasized that the diagnoses which were made in these aspiration biopsies

STRENGTH-INTERVAL CURVES AND REPETITIVE STIMULI IN ELECTRODIAGNOSIS

LEWIS J POLLOCK M D JAMES G GOLSETH Lieutenant (j.g.) M.C. U.S.N.R. and
ALEX J ARIEFF M D Chicago Illinois

REPETITIVE stimuli have been used by physiologists and clinicians to study the kinetics of stimulus for many years. The best known repetitive stimulus used by clinicians has been the faradic current. Because however it usually has an uncontrollable waveform is variable in duration, amplitude and repetition frequency it is of limited value for obtaining data.

Another repetitive stimulus often used by physiologists is the alternating sine wave of variable frequency. Since there is no appreciable time interval between stimuli it does not correspond to the conditions studied in this work.

Repetitive stimuli separated by a controllable interval of time have been studied chiefly by physiologists. For example there are the paired stimuli as studied by among others Hill and Solandt the recurrent discharges of condensers studied by Lapicque Chauchard and Albert and unidirectional periodic current or Leduc current studied by May.

The data obtained from such studies have been plotted as strength frequency curves in which the frequency was changed by varying both the duration of the stimulus and the time interval between stimuli. The data were also plotted as strength interval curves in which the duration of the stimulus was held constant and the time intervals between them varied.

Because the duration of stimuli and likewise the time intervals between them varied so much from investigator to investigator the literature contains very few clues which aid one in selecting appropriate values for electrodiagnosis. For example, for the purpose of his

investigation it was necessary for Solandt to use stimuli lasting 2 000 milliseconds. Lapicque Chauchard and Albert used time intervals between stimuli ranging from 833 to 2 000 milliseconds. Only by analysis of these data as well as those of Scott and May could one find some suggestions applicable to our problem.

From such analysis it appeared that characteristics to be studied were (1) *Addition Latente* or recruitment (2) the profile of the strength interval curve, and (3) a search for a possible optimum interval and limiting interval time.

MATERIAL AND METHOD

The material consisted of 6 cats in which section and immediate suture of the left sciatic nerve was done.

The first strength interval curves were obtained on about the 7th postoperative day and at approximately weekly intervals thereafter until clinical recovery was well advanced.

For this study, a constant current impulse stimulator was designed by one of us (J G G) and Mr J A. Fizzell which entailed the following features: (1) constant predetermined values of stimulating current irrespective of rather great changes in tissue impedance (2) seventeen durations of stimulating current ranging from 1 millisecond to 1 500 milliseconds these selected to conform to a logarithmic scale (3) nine values of intervals between stimuli ranging from 1 to 4 000 milliseconds (Fig 1).

In making a systematic approach to the problem mentioned above we elected to hold the duration of the stimulus constant at 5 milliseconds and to vary the durations of the interval employing those of 1 5 10 15 20 25 and 30 milliseconds. When the duration of stimuli was held constant at 1 millisecond, it was found that some time after section the threshold exceeded the amount of available current.

From the Department of Nervous and Mental Diseases, Northwestern University Medical School.

The work described in this paper was carried on under a contract which had initially the Office of Scientific Research and Development and subsequently the Office of the Surgeon General, U. S. Army as financial sponsors.

Fig. 2 Facilitation ratio expressing both facilitation and inhibition versus postoperative days. The duration of the stimulus was 5 milliseconds the interval was 1 millisecond the end point was a twitch. Facilitation ratio = I/I_1 where I_1 = the threshold current for a single stimulus and I = the threshold current for repetitive stimuli

val of 1 millisecond. We shall describe first the change in the facilitation noticed during the periods of degeneration, denervation and regeneration using a twitch as the end point.

In the normal the facilitation ratio ranged from 1.1 to 1.7 with an average value of 1.3. Following section and suture of the sciatic nerve of the cat, the evaluation of changes in facilitation and the facilitation ratio followed closely the changes in rheobase and galvanic tetanus ratio. Thus early in degeneration there was an increase in the facilitation ratio followed by a decrease and secondary increase. During denervation the ratio became the highest but early in regeneration it dropped off and usually was at a low value by the 70th postoperative day. It should be pointed out that in several cases there was a decrease and increase in the ratio early in regeneration which was then followed by a progressive diminution in the ratio to a low value. In several instances the ratio became less than 1.0 during the period of regeneration thus indicating that inhibition was present (Fig. 2).

When on the other hand the duration of the stimulus was 5 milliseconds and the interval between stimuli was 0 milliseconds inhibition was observed in some cases during early degeneration and was present in all cases during late regeneration. It is to be remem-

Fig. 3 Facilitation ratio expressing both facilitation and inhibition versus postoperative days. The duration of the stimulus was 5 milliseconds the interval 30 milliseconds the end point a twitch.

bered that a facilitation ratio of less than 1.0 denotes inhibition (Fig. 3).

Because the liminal twitch is difficult to reproduce as in the case of other investigators we have preferred to use sustained tetanus as the end point of stimulation. Under this condition in the case of normal muscle, the threshold current for repetitive stimuli usually diminished as the time interval between stimuli was increased. Following section and suture, there was an initial increase in the facilitation ratio followed by a sharp decrease to below 1.0 indicating inhibition. During denervation the greatest facilitation occurred and during the period of recovery there was a continued decrease in the ratio occasionally followed by a temporary increase but leading to a final inhibition (Fig. 4).

C, repetitive stimuli—5 millisecond's duration, 5 millisecond's interval. D, repetitive stimuli—5 millisecond's duration, 1 millisecond's interval.

RESULTS

Facilitation and inhibition Kries and Sewall called attention to what was called *Addition Latente* in 1881:

Facilitation or recruitment has been expressed as follows. A very short subthreshold stimulus leaves behind it a local change of excitability which gradually dies away, so that a second subthreshold stimulus although separated from the first by a finite time interval, may sum with it and become effective.

The change of excitability has been said by Hill and Solandt to depend upon the function of accommodation and from curves obtained by them, they measured the time rate of accommodation.

It was pointed out by Lapicque that *Addition Latente* occurs when the duration of each stimulus is brief as compared to the chronaxie. As will be seen this is usually true when the intervals are of short duration but if the intervals are of longer duration not only does facilitation cease but actual inhibition may occur.

The term facilitation as defined above denotes that a muscle is more excitable to re-

petitive stimuli having a specified duration and time interval than to a single stimulus of the same duration. The term inhibition on the other hand denotes that a muscle is less excitable to repetitive stimuli than to a single stimulus. For the purpose of showing how facilitation and inhibition vary during the periods of degeneration, denervation, and regeneration it is desirable to express these two terms in some mathematical form. One convenient method of doing this is to take the ratio of the threshold current for a single stimulus of a certain duration to the threshold current for repetitive stimuli of the same duration and plot this number as a function of postoperative days on suitable graph paper. The ratio just described may be termed the facilitation ratio and expressed in equation form it becomes

$$\text{Facilitation ratio} = \frac{I_1}{I_r} \text{ where } I_1 = \text{the threshold current for a single stimulus and } I_r = \text{the threshold current for repetitive stimuli}$$

When using this equation a ratio of 1.0 indicates the condition where neither facilitation nor inhibition exists. Facilitation is present when this ratio is a number greater than 1.0 and, conversely inhibition is present when this ratio is a number less than 1.0. The curves in Figures 2, 3, 4, and 5 have been computed by means of the facilitation ratio formula just described and plotted on semilogarithmic coordinate paper.

In our study the durations of the stimuli were 1 and 5 milliseconds. When the duration of the stimulus was only 1 millisecond it was found that as denervation occurred the threshold rose to such a degree that often data could not be obtained. Therefore, in this study we will report the data resulting from stimuli of 5 milliseconds duration with intervals of 1, 5, 10, 15, 20, 25, and 30 milliseconds.

The liminal response of muscle to repetitive stimulation is a twitch. Although this end point is difficult to reproduce, the data obtained in this manner will be reported since they may become valuable in mathematical treatment of the kinetics of stimulus. Since facilitation was observed best when the interval was 1 millisecond the first study was made using a stimulus of 5 milliseconds and an inter-

Fig. 2. Facilitation ratio expressing both facilitation and inhibition versus postoperative days. The duration of the stimulus was 5 milliseconds, the interval was 1 millisecond and the end point was a twitch. Facilitation ratio = I_0/I where I_0 = the threshold current for a single stimulus and I = the threshold current for repetitive stimuli.

val of 1 millisecond. We shall describe first the change in the facilitation noticed during the periods of degeneration denervation and regeneration using a twitch as the end point.

In the normal the facilitation ratio ranged from 1 to 1.7 with an average value of 1.3. Following section and suture of the sciatic nerve of the cat the evaluation of changes in facilitation and the facilitation ratio followed closely the changes in rheobase and galvanic tetanus ratio. Thus early in degeneration there was an increase in the facilitation ratio followed by a decrease and secondary increase. During denervation the ratio became the highest but early in regeneration it dropped off and usually was at a low value by the 70th postoperative day. It should be pointed out that in several cases there was a decrease and increase in the ratio early in regeneration which was then followed by a progressive diminution in the ratio to a low value. In several instances the ratio became less than 1.0 during the period of regeneration thus indicating that inhibition was present (Fig. 2).

When on the other hand the duration of the stimulus was 5 milliseconds and the interval between stimuli was 30 milliseconds inhibition was observed in some cases during early degeneration and was present in all cases during late regeneration. It is to be remem-

Fig. 3. Facilitation ratio expressing both facilitation and inhibition versus postoperative days. The duration of the stimulus was 5 milliseconds, the interval, 30 milliseconds and the end point a twitch.

bered that a facilitation ratio of less than 1.0 denotes inhibition (Fig. 3).

Because the liminal twitch is difficult to reproduce as in the case of other investigators we have preferred to use sustained tetanus as the end point of stimulation. Under this condition in the case of normal muscle the threshold current for repetitive stimuli usually diminished as the time interval between stimuli was increased. Following section and suture there was an initial increase in the facilitation ratio followed by a sharp decrease to below 1.0 indicating inhibition. During denervation the greatest facilitation occurred and during the period of recovery there was a continued decrease in the ratio occasionally followed by a temporary increase but leading to a final inhibition (Fig. 4).

Fig. 4. Facilitation ratio expressing both facilitation and inhibition versus postoperative days. The duration of the stimulus was 5 milliseconds, the interval 1 millisecond and the end point tetanus.

Fig. 5. Comparison of the facilitation ratio to chronaxie on various days after operation. The duration of the stimulus was 5 milliseconds, the interval, millisecond the end point, tetanus.

Confirming Lapicque's observation it was found that with intervals of short duration a lengthening of chronaxie was accompanied by an increase in the facilitation ratio and conversely when the chronaxie shortened the facilitation ratio decreased (Fig. 5).

THE PROFILE OF STRENGTH INTERVAL CURVES

Lapicque said in the case of muscle directly stimulated by means of a given capacity the liminal voltage is constant for very small intervals then as the interval increases, it goes up gradually until it reaches the threshold of an isolated stimulus (infinite interval). This should not be misinterpreted as meaning a stimulus of infinite duration which would be the rheobase value of voltage.

May also reported that with stimuli of 5 milliseconds duration the strength of the contraction increased with increasing frequency to 120 per second and then remained constant. It is permissible for us to assume that for liminal stimulus the threshold would have diminished with shorter intervals. Thus we were unable to confirm in the case of normal muscle. On the contrary we found that as the interval increased up to 30 milliseconds the threshold diminished as was the case in Solandt's work.

Fig. 6. Interval ratio versus postoperative days. The duration of the stimulus was 5 milliseconds in each instance. Interval ratio = T_{10}/T where T_{10} = the threshold current for an interval of 10 milliseconds and T = the threshold current for an interval of 1 millisecond.

In a few instances an optimum interval was observed as had been observed by May. However an optimum interval was at times more clearly demonstrated on the 6th or 7th postoperative day.

In a strength interval curve obtained from degenerating denervated and early recovering muscle the magnitude of the threshold current generally rises as the length of the interval is increased according to the state of muscle whether denervated or recovering. This continues up to a point where a plateau is reached and a further lengthening of the interval causes no further rise in the threshold. In fact as recovery occurs the threshold may even decrease. This interval at which the plateau is reached is known as the limiting interval. At about the 7th postoperative day the strength interval curve is so nearly flat that there is no definite limiting interval. During the period from about the 7th to the 40th postoperative day the limiting interval becomes longer and longer until recovery begins.

At the 40th postoperative day in some cases no plateau was noticed even at an interval of 30 milliseconds. Thereafter as neurotization was taking place the limiting interval began to reappear at shorter intervals until at the 70th postoperative day the strength interval curve became nearly flat and resembled the

normal. Although this phenomenon of limiting interval" was observed in all cases the lack of uniformity with which the limiting interval diminished during the process of neurotization seems to us to render it an inaccurate index of recovery.

On the other hand, the steepness of the rise of the strength interval curve was seen to change appreciably during the periods of degeneration, denervation and regeneration. For example the rise of the curve for denervated muscle was usually quite steep. However as recovery began and progressed the rise became less and less steep finally at about the 70th postoperative day the curve was almost flat. These changes in the rise of the curve can be visualized quite readily if one plots the ratio of only two points on the strength interval curve as a function of postoperative days.

The points we elected to use were the threshold current for an interval of 15 milliseconds and the threshold current for an interval of 1 held constant at 5 milliseconds. The ratio obtained by dividing the threshold current for an interval 15 milliseconds by the threshold current for an interval of 1 millisecond is termed the interval ratio and is plotted as a function of postoperative days (Fig. 6). It should be remembered that a high interval ratio denotes a steep rise in the strength interval curve whereas a low ratio denotes a more gradual rise or even a flat curve.

In the normal the interval ratio is usually less than 1.0 and occasionally during early degeneration a ratio of less than 1.0 was observed. As denervation progresses however the ratio becomes some multiple of 1.0 and by the 30th to 40th postoperative day has reached its highest value at times as high as 5.0. As regeneration began and progressed the ratio took on smaller and smaller values until about the 70th postoperative day when it again became a number less than 1.0.

APPLICATION TO MAN

When we began to study strength interval curves in man we had no guide as to which duration of stimulus and time interval between stimuli would give the most satisfactory data. We elected to use a stimulus of 1 millisecond

duration and intervals of 1, 5 and 12 milliseconds respectively.

This proved to be an unfortunate choice for two reasons. First when a muscle is denervated it is often impossible to obtain data for a single stimulus of less than 14 to 30 milliseconds duration a fact which prevented us from making a quantitative study of facilitation and inhibition. Second because the threshold values of current for the longer time intervals increased so rapidly especially during denervation we were unable to obtain satisfactory data studying the steepness of rise of the strength interval curve.

Although we are able to say from data obtained in human material that a flat strength interval curve is indicative of advanced recovery we feel that the subject of strength interval curves for electrodiagnosis in man needs restudy.

It is suggested for the benefit of those who may desire to undertake such an investigation that a stimulus of 30 milliseconds duration and time intervals of 1, 5 and 15 milliseconds be tried. This would ensure the obtaining of data for a single stimulus at all times and permit an evaluation of facilitation and inhibition. In addition a stimulus of 5 milliseconds duration should give satisfactory data for studying the steepness of the rise of the strength interval curve after injury to the nerve.

From our investigation it would appear that longer intervals than those mentioned above could offer very little because a limiting interval soon occurs for a stimulus having a duration of 20 or more milliseconds.

SUMMARY

We have reported on the experimental data obtained from strength interval curves in the tibialis anticus muscle of the cat during the periods of degeneration, denervation and regeneration following section and immediate suture of the sciatic nerve. While changes in facilitation ratio obtained using a twitch as an end point were described to permit of any study of the kinetics of stimulus it was pointed out that the change in facilitation ratio obtained when using tetanus as the end point gave a more accurate and critical assessment

of the muscle on the various postoperative days. Attention was then called to the fact that the limiting interval was an unsatisfactory index of recovery because of the lack of uniformity with which it diminished during the process of neurotization. It was next shown that the steepness of the rise of the strength-interval curves which was expressed in terms of an interval ratio gave reliable information as to the state of the muscle on the various postoperative days.

The applications of strength-interval curves for electrodiagnosis in man were discussed and at that time we pointed out the reasons for our failure to obtain satisfactory data in a large number of cases. We then suggested several changes in technique which should be useful to future investigators in this field

CONCLUSIONS

1. *Addition Latente* or facilitation whereby the threshold for repetitive stimuli of short duration is less than that for a single stimulus of same duration was found in normal muscle

2. Facilitation was found to be greatest in completely denervated muscle.

3. With the beginning of regeneration, facilitation progressively diminished and finally inhibition occurred

4. Although during the period of degeneration and regeneration a limiting interval was found it proved inconclusive in making a diagnosis

5. The steepness of the rise of the strength interval curve becomes greater as degeneration progresses is greatest during denervation, and becomes less and less during recovery

CECOSTOMY AND THE MILLER-ABBOTT TUBE

A Report on their Combined Use in the Preparation of the Obstructed Large Bowel for Surgery

JOHN BRADFORD MILLET M D Boston Massachusetts

DECOMPRESSSION and preparation of the colon preliminary to resection of obstructing neoplasms of the left colon are usually accomplished by cecostomy or transverse colostomy. There are several difficulties associated with both methods. A cecostomy accomplishes decompression without complete defunctioning and does not usually permit cleansing of the bowel proximal to the lesion. For these reasons it may be inadequate and a transverse colostomy may be required for proper preparation of the bowel before resection of the growth. A defunctioning transverse colostomy permits irrigation of the isolated bowel proximal to the lesion and is in that respect preferable to cecostomy but it necessitates a further major operative procedure—not without hazard—namely that of closure.

For these reasons the author has sought a more adequate method of large bowel preparation using a cecostomy and therefore not requiring secondary closure. Such a method is the subject of the present communication.

Decompression by cecostomy is performed according to the method of Allen and Welch. Figures 1 and 2 show diagrammatically the type of cecostomy used and the manner in which the Miller Abbott tube is inserted. A large cecostomy tube of 20 millimeter diameter is recommended. Following this procedure a few days of rest are felt advisable so that the colon may regain its tone and resume peristalsis. Three or 4 days have been found quite adequate. A small hole is then cut in the superior aspect of the rubber drainage tube close to its attachment to the cecostomy tube and a Miller Abbott tube (1-4) (preferably size No. 18) is passed into the cecum and the balloon then inflated with 60 to 120 cubic centi-

meters of air. The curved passage through the cecostomy tube offers such resistance to the Miller Abbott tube that it must be manually urged into the cecum. What slack is available in the cecum is readily taken up by the action of peristalsis on the balloon. If the Miller Abbott tube is readjusted and slack placed into the cecum as often as every 10 minutes the tip of the tube may reach the sigmoid flexure within 3 hours. The tube appears to progress equally well on or off suction and it is advisable not to use suction at this time lest the tube become occluded. When the cecum will no longer accept slack tube it is probable that the obstructing lesion has been reached. This fact may be checked by x ray examination. The balloon is then deflated and the tube is made fast externally by strapping it to the cecostomy. Even though a maximum of a yard of tube is necessary we have not shortened the Miller Abbott tube because its length has not interfered with its function in these cases.

Irrigations through the Miller Abbott tube of 1500 cubic centimeters of normal saline solution or tap water twice daily will back flush the colon from the point of obstruction and the drainage will flow from the cecostomy tube. Following each irrigation the Miller Abbott tube is placed on Nelson or Wangensteen suction for 30 minutes to empty the bowel lumen of residual irrigating fluid and to maintain the bowel in a state of decompression. Following this a suspension of sulfathalidine has been instilled into the Miller Abbott tube in some patients. Regardless of this use of sulfathalidine there has been no gross difference in the appearance of the bowel at the time of resection and open anastomosis. We have found it convenient to use the ordinary intravenous saline flasks and tubing as the connections fit the Miller Abbott tube. In a day

Fig. 1. Diagrammatic sketch of cecostomy incision, cecostomy tube, and insertion of Miller Abbott tube.

or so the obstructing lesion may open sufficiently to permit the irrigations to be given with the patient on the bedpan as both rectal and retrograde colonic irrigation may take place.

Resection can be carried out on a clean bowel when the patient is adequately prepared systematically to withstand the pro-

Fig. 2. Diagrammatic sketch in longitudinal section showing manner of insertion of cecostomy tube and of Miller Abbott tube. The cecum is closed about the cecostomy tube by 3 invaginating pursestring sutures, the first being of No. 0 plain catgut which includes a bite into the tube itself for fixation; the remaining 2 being of No. chromic catgut. The omentum is wrapped about the cecostomy tube prior to closure of the abdomen. The right angle glass tube with its attached rubber tubing is used to prevent kinking and has an inside diameter of 30 millimeters. Procedure often about 10 days after cecostomy. The last irrigation is given 2 or 3 hours prior to

Fig. 3. Case. X-ray film on entry showing marked dilatation of the colon.

Fig. 4. Case. X-ray film showing the passage of the Miller Abbott tube 3 hours after insertion.

operation and is followed by suction. Both sulfathalidine by mouth 6 to 8 grams daily, and a low residue diet are indicated to keep the cecostomy drainage of such a character as to allow the Miller Abbott tube and the cecostomy tube to function at their best.

It is suggested though this procedure has not yet been put to the test, that cleansing of the distal limb of the bowel in transverse colostomies may also be successfully accomplished through the use of the Miller Abbott tube and irrigations.

CASE 1 M D No 546942 (Figs 3 and 4.) a 73 year old woman entered the Massachusetts General Hospital with a story of complete large bowel obstruction of 48 hours duration. An x ray examination of the abdomen showed a markedly distended large bowel and a barium enema revealed total obstruction in the region of the proximal sigmoid flexure. A cecostomy was performed with satisfactory decompression and by the fourth postoperative day she had regained normal peristalsis. A Miller Abbott tube was passed through the cecostomy and irrigations were instituted. Eleven days following the initial procedure resection and open end-to-end anastomosis were carried out at which time the bowel was clean and decompressed with no visible fecal matter. There was also no discrepancy of significance in the diameter of the two limbs of sigmoid at the point of anastomosis.

Fig. 5. Case 1. X ray film on entry showing distention of small and large bowel.

CASE 2 S DeG No 547698 (Figs 5 and 6) a 69 year old man entered the Massachusetts General Hospital with a story of complete bowel obstruction of 48 hours duration. An x ray examination of the abdomen showed dilated small and large bowel. Barium enema demonstrated an obstructing lesion in the midsigmoid consistent with carcinoma. A Harris tube was passed into the small bowel but as improvement did not occur in the course of 48 hours cecostomy was performed with fair decompression. On the third postoperative day peristalsis had returned to normal and a Miller Abbott tube was passed through the cecostomy and irrigations were instituted. Sixteen days after cecostomy resection and open end-to-end anastomosis were carried out. At this time the bowel was clean and well decompressed with no feces present grossly and no significant discrepancy in the diameter of the bowel proximal and distal to the resected area.

CASE 3 E W No 552300, a 64 year old woman entered the hospital with partial large bowel obstruction and a distended cecum secondary to a carcinoma of the rectum. Cecostomy was carried out with good decompression and 5 days later a Miller Abbott tube was passed through the cecostomy. Irrigations were instituted and 12 days following her initial procedure a combined abdominoperineal resection of her rectum was performed. At this time the bowel was found completely decompressed and in very satisfactory condition for the resection.

CASE 4 A B No 472577 a 75 year old man entered the Massachusetts General Hospital with 4

Fig. 6. Case 2. X ray film showing the passage of the Miller Abbott tube 2 hours after its insertion.

lay a total large bowel obstruction from an extensive carcinoma of the rectosigmoid. Cecostomy was performed and 4 days later a Miller Abbott tube was inserted into the cecostomy and irrigations instituted. Despite much impacted barium in the ascending colon the Miller Abbott tube progressed slowly and steadily to reach the splenic flexure in 5 days. Fourteen days following cecostomy exploratory laparotomy was carried out and a permanent sigmoid colostomy made because the growth was found to be locally inoperable. At this time the bowel was found to be completely cleansed.

CASE 5. M. D. No. 548717. A 67 year old woman entered the hospital with a story of progressive recurrent attacks of gaseous distention and abdominal cramps culminating in nearly complete large bowel obstruction for a month prior to entry. Barium enema showed an extensive area of rather marked narrowing in the mid and upper sigmoid flexure. Cecostomy was performed and on the fourth post operative day when peristalsis had resumed normal activity a Miller Abbott tube was passed through the cecostomy. It progressed without difficulty and irrigations were started. On the fifteenth day after cecostomy resection of an area of diverticulitis in the lower sigmoid flexure and open end-to-end anastomosis were done. At the time of resection the bowel was deflated but had a minimal amount of feces present. This patient had no irrigations or suction applied through her Miller Abbott tube during the 24 hour period prior to operation.

CASE 6. M. G. No. 8384. A 60 year old woman entered the hospital with a story of subacute large bowel obstruction of 14 days duration. Barium enema showed complete obstruction from below at the splenic flexure. Cecostomy was performed with poor decompression and the patient continued to have a moderately dilated colon proximal to the obstruction with associated cramps. On the tenth

postoperative day a Miller Abbott tube was passed without difficulty through the cecostomy and irrigations were instituted—with complete relief to the patient and clinical decompression of the colon proximal to the obstruction. Four days following passage of the Miller Abbott tube resection of the carcinoma of the splenic flexure with open end-to-end anastomosis was carried out at which time the bowel was deflated and clean.

SUMMARY

A method of preparing patients with obstructing lesions of the left colon for resection is presented together with several illustrative case reports. This method consists of cecostomy and the passage of a Miller Abbott tube through the cecostomy for the purpose of back flushing the colon by irrigations. It is also useful for postoperative decompression of the anastomosis. It is felt that this method offers advantages over cecostomy alone and it is also believed to be superior to a transverse colostomy because a secondary operative closure is not required.

SUPRACONDYLAR SHORTENING OF THE FEMUR FOR LEG LENGTH INEQUALITY

ROBERT DUNHAM MOORE, M.D. Chicago, Illinois

LENGTH inequality of the lower limbs in the growing child may be corrected by elective arrestment of growth of one or more growth cartilages of the longer limb as described by Phemister. After puberty the rate of longitudinal growth from the femoral and tibial growth cartilages declines and marked length discrepancy usually cannot be corrected by this method. In the adolescent or adult with excessive length inequality the deformity can only be corrected by shortening the longer limb or lengthening the shorter extremity.

Individuals with one deformed leg frequently object to the risk of impairment of the sound limb occasioned by surgical shortening. Experience has shown however that leg shortening is associated with few complications when compared with leg lengthening. The formidable procedure of lengthening with its greater incidence of nonunion, postoperative infection or traction damage to nerves, vessels and muscle leaves many surgeons reticent to perform such a procedure. This is particularly so where marked disuse atrophy of bone and soft tissues provides unfavorable conditions in the short limb. Partially paralyzed muscles may be weakened by lengthening and ankylosis of a joint on either side of a lengthened long bone increases the hazard of fracture through the site of the lengthening. The relative safety of femoral shortening permits wider application of this method of leg length equalization than is the case with femoral lengthening.

The usual site of election for shortening the femur in published cases is the diaphysis. It is the purpose of this paper to describe the technique used and end results of 15 cases in which shortening was accomplished by resection of bone from the lower femoral metaphysis.

From the Department of Surgery, Division of Orthopedic Surgery, The University of Chicago.

PRINCIPLES INVOLVED IN LEG SHORTENING

The object of shortening is to equalize the length of the limbs or to reduce the discrepancy to an amount compatible with good function. Leg length inequality of less than 1 inch is seldom of functional significance. A discrepancy of 1 inch or more may be sufficient to impair gait appearance and dynamics of the back or unaffected limb. Lengthening the shortened limb is esthetically more desirable from the patient's standpoint but the decision to shorten the longer limb or lengthen the shorter leg can be made only after comprehensive study of the individual case.

Leg shortening usually should be performed near the end of the growth period. The accuracy with which equalization is accomplished by this method is nullified if subsequent unequal growth occurs. The earlier decline in the rate of growth of the lower extremities in girls generally permits operative shortening at the age of 12 or 13 years. In boys in whom puberty occurs later and growth from the lower extremity is relatively greater, equalization by shortening should be delayed until 14 or 15 years of age. Final decision rests in correct evaluation of the maturity of the individual at a given age based on knowledge of his hereditary background, bone age and growth expectancy of the sound limb as well as the affected leg.

Flexion adduction deformity of the hip or any angulation deformity of the limb must be corrected before evaluation of actual leg length inequality is possible. Correction of fixed hip deformity is usually done near the end of the growth period if recurrence of the deformity is to be prevented.

In patients with weak hip abductors or inability to elevate the pelvis on the short limb, side $\frac{1}{2}$ to 1 inch of residual shortening of the leg facilitates walking. This also may be true in patients with ankylosis of either a hip or knee.

Fig. 1. Drawing showing the technique of resection of bone from the metaphysis and method of end-to-end fixation over intramedullary peg with screw or threaded pins.

The maximum correction advisable by shortening in the lower $\frac{2}{3}$ of the femur is about 3 inches. Shortening in excess of this amount may produce permanent quadriceps weakness. If length inequality is more than 4 inches, shortening the longer limb may be preceded by lengthening the shorter leg. Partial equalization of length by resection may be advisable if the patient would be rendered unduly short of stature leaving a difference of 1 or 2 inches to be compensated for by a built up shoe. These factors should be considered in planning any length equalization procedure.

CAUSES OF UNEQUAL LEG LENGTH

Congenital anomalies accounted for marked length discrepancy of the legs in 3 cases reported here. Congenital dislocation of the hip of 12 years' duration with chronic disability from pain led to retardation of growth from all growth cartilages of the affected limb in 1 case. In such instances dysplasia of the proximal femoral growth cartilages associated with the disturbed development of acetabulum and capital epiphysis may be a contributing factor to the shortening. Congenital hypoplasia and a short cavus foot resulted in marked shortening of the limb and conspicuous limp in an

other instance. Dyschondroplasia with involvement of one leg was accompanied by retarded growth and premature ossification of growth cartilages in a third case.

Tuberculous arthritis of the hip with extensive destruction of acetabulum and capital epiphysis caused shortening in 6 cases. Similar destruction of the joint from severe pyogenic arthritis accounted for shortening in 3 cases. In 2 patients with tuberculous arthritis and 1 with pyogenic infection of the hip prolonged disability led to severe retardation of growth from all epiphyses of the affected limb. In the latter case premature ossification of the medial part of the upper tibial growth cartilage led to a tibia vara deformity before growth was complete. In such cases eccentric or central ossification of the cartilage leads to localized bone bridging between epiphysis and metaphysis as demonstrated by Gill and Ross. Eccentric bony bridging produces angulation deformity when subsequent weight bearing stimulates growth from remaining cartilage. The resulting angulation deformity further contributes to the shortening.

Osteomyelitis of the shaft of the femur with prolonged disability led to retarded growth from all growth cartilages of the affected limb and premature ossification of the upper tibial growth cartilage in 1 case in this series.

Residual paralysis following poliomyelitis was responsible for retarded growth of the leg in the remaining 2 cases. Reduced functional stimulation or nutritional disturbances associated with altered blood flow through the extremity may account for such inhibition of longitudinal growth in paralyzed limbs.

OPERATIVE TECHNIQUE

The history of leg shortening operations has recently been reviewed by White, Howorth and Phalen and Chatterton making repetition unnecessary.

The technique of resection and fixation of the apposed bone ends with an intramedullary peg fashioned from the resected bone has previously been employed by Taylor, Calvé, Royle, Ritter, Groves, Moore, Camera, Harmon and Krigten and Howorth. The method used here is similar in principle and differs only in location of the sight of resection.

Fig. 2a

Fig. 2. Case 1. a, The patient before operation (left) and 5 years and 5 months after shortening the left femur 2 inches (right). b, Distal end of the left femur 8 weeks after the shortening operation. The osseous grafts have united and ossified callus bridges the bone ends. c, Distal end of the left femur 2 years and 5 months after the shortening operation.

A bloodless field is obtained by application of an Esmarch bandage high on the thigh. Through a 7 inch lateral incision over the distal end of the femur the fascia lata is incised and the vastus lateralis muscle identified. The muscle is reflected anteriorly from the intermuscular septum.

The lowermost anterior perforating branches of the profunda femoris artery and vein are identified, ligated and cut. The periosteum is incised longitudinally and elevated from the circumference of the metaphysis over the segment to be excised. The segment of bone to be removed is marked with a chisel and the distal osteotomy is made first with a Gigli saw. The shaft of the femur may then be displaced outward and the proximal osteotomy with the Gigli saw facilitated.

Fig. 2b

Fig. 2c

The resected segment is divided longitudinally into several parts with the motor saw and one portion is used for the intramedullary graft. One-half of the graft is inserted into the proximal shaft. A hole is drilled through the outer cortex graft, and inner cortex and a transfixion screw or threaded pin is inserted. The protruding half of the graft is then intro-

Fig. 3. Case 2. a, The patient at 7 years of age before leg length equalization procedures are done. There is abduction deformity of the left hip, tibia vara, and 7 3/4 inches shortening of the left leg. Osteotomies of the hip and upper tibia and fibula are followed by lengthening the left tibia and fibula 4 inches. b, The patient at 9 years of age, 9 years after the right femur was shortened 4 inches.

duced into the metaphysis and likewise secured with a transfixion screw.

The remaining pieces of the resected segment are used as onlay grafts as shown in Figure 1 and may be ligated in place with cat gut. The soft parts are approximated in the usual manner.

Postoperative immobilization in a single hip spica plaster dressing for 6 to 8 weeks is followed by weight bearing in a tubular plaster dressing until bony union is complete.

Quadriceps exercises are encouraged during the period of immobilization and active knee exercises are continued after removal of the support.

CASE REPORTS

Congenital hypoplasia associated with a short cavus foot was responsible for 2 inches of shortening of the right leg in the following

Fig. 4. Case 3. a, The patient, 3 years and 7 months after devolution osteotomy and arthrodesis of the right hip for unreduced congenital dislocation (left). b, The appearance 6 months later after shortening the left femur 4 inches.

case. Exact equalization of limb length was accomplished in this instance.

CASE 1 (Case No. 9, Table I). B. H., aged 14 years, had deformity of the right foot at birth and shortening of the limb was first noted at 2 years of age. Her father had similar deformity of the right foot but no shortening of the limb or disability.

Examination revealed 2 inches of shortening of the right leg. There was cavus deformity of the right foot which was smaller than the left. There was no impairment of sensation or motor power.

The length of the limbs was equalized by shortening the left femur 2 1/2 inches. Figure 2a shows the patient before operation and 2 years and 5 months after the femoral shortening operation. Figure 2b shows the roentgenographic appearance of the left femur 8 weeks after operation.

Figure 2c shows the result 2 years and 5 months later at 16 years of age. The length of the legs was equal at that time.

Prolonged disability from infectious arthritis of the hip at 4 years of age was followed by premature ossification of the lower femoral

Fig 5a.

Fig 5 Case 4. a, The patient at 6 years of age with a centimeters shortening of the left leg (left). On the right the same patient at 15 years of age 7 months after shortening the right femur $1\frac{3}{4}$ inches. b, Distal end of the right femur 7½ weeks after operation. c, Distal end of the right femur 2 years and 6 months after the shortening operation.

Fig 5b

upper and lower tibial growth cartilages in the following case. Marked retardation and early arrestment of growth from all growth cartilages including those destroyed by the hip disease produced $7\frac{1}{4}$ inches relative shortening. Hip deformity and tibia vara accounted for part of the shortening. Complete equalization could not be accomplished in this instance because of marked length discrepancy and short stature of the patient.

CASE 2 (Case No. 4, Table I) J. P. aged 17 years had infectious arthritis of the left hip at 4 years of age. The limb was immobilized in a plaster hip spica dressing for 3 years during which drainage was present. A long leg brace was worn for an additional 7 years. Ankylosis of the joint occurred during the fifth year of the disease. Ten years after onset subtrochanteric osteotomy was done and the brace discarded. She was first seen at the University of Chicago Clinics 3 years later at 17 years of age. Examination showed ankylosis of the left hip in approximately 20 degrees of abduction and 30 degrees of flexion. There was varus deformity of the proximal end of the tibia with marked overgrowth and bowing of the fibula. The left limb was $7\frac{1}{4}$ inches shorter than the right.

Fig 5c.

Hip deformity and varus deformity of the tibia were corrected by osteotomies of the upper femur, tibia, and fibula. The left tibia and fibula were then lengthened $2\frac{3}{4}$ inches. Five months later the right femur was shortened $2\frac{3}{4}$ inches. Residual shortening of the left limb is approximately $1\frac{1}{4}$ inches. Figure 3a shows appearance of patient on admission. Figure 3b shows same patient 1 year after operation. Gait is good and she has no back disability from pelvic tilt $3\frac{1}{2}$ years after last operation.

Fig. 6. Case 5. a, Appearance of the patient at 4 years of age before operation. b, The patient 3 months after shortening the right femur $\frac{3}{4}$ inches.

Unreduced congenital dislocation of the right hip with retarded growth from disuse accounted for marked shortening of the limb in the following case. After operative reduction and arthrodesis of the hip 3 inches of residual shortening of the affected limb was partially corrected by resection of $2\frac{3}{4}$ inches from the lower femoral metaphysis of the left femur.

CASE 3 (Case No. 5 Table I). H. M. aged 15 years was first examined for untreated congenital dislocation of the right hip at 12 years of age. Shortening limb and pain in the right thigh after exercise had been noted since she first walked. Two older sisters had been treated for bilateral congenital dislocation of the hip.

Examination revealed shortening of approximately $4\frac{1}{4}$ inches when standing. Approximately 3 inches could be accounted for by upward displacement of the femur. Trendelenburg's sign was positive and there was marked limp.

Two years and 7 months after derotation osteotomy and arthrodesis of the hip, there was 3 inches residual difference in leg length. The discrepancy was reduced to $\frac{3}{4}$ inch by resection of $3\frac{1}{4}$ inches from the

left lower femoral metaphysis. Figure 4 shows the patient before the left femur was shortened and the appearance 6 months after resection of $3\frac{1}{4}$ inches from the left lower femoral metaphysis.

Severe residual paralysis of trunk and lower extremities following poliomyelitis at 21 months of age led to unequal growth of the lower extremities and length inequality of $1\frac{1}{4}$ inches in the following case.

CASE 4 (Case No. 8 Table I). S. M. aged 14 years, had acute anterior poliomyelitis at 1 year and

9 months of age with severe residual paralysis of the trunk and lower extremities. At 6 years of age caliper braces and a Hoke corset were provided. He was able to walk short distances with crutches but was severely disabled. Two centimeters of shortening of the left leg at 7 years of age increased to 3.5 centimeters in the following 6 years. Correction of this discrepancy by epiphyseal arrest was not believed indicated because of his limited ability to walk. At 13 years of age subluxation and instability of the left hip necessitated arthrodesis of the joint. This was followed by bilateral triple arthrodesis. These procedures were followed by marked improvement in gait. In the presence of weak trunk musculature and inability to elevate the right side of the pelvis it was believed that further improvement would follow equalization of the length of the legs. Accordingly the right femur was shortened $1\frac{3}{4}$ inches. Figure 5a shows the patient at 6 years of age and at 14 years of age following arthrodesis of the left hip, stabilization of both feet and shortening the right femur.

Figure 5b shows the roentgenographic appearance approximately 2 months after the shortening operation. Figure 5c shows the lower end of the femur 2 years and 6 months later. He walks well with one cane and is able to walk short distances without support.

Chondrodystrophy of the left femur and tibia in the following case resulted in premature ossification of the growth cartilages at the knee with 3 inches of shortening of the leg when growth was complete. Partial equalization of length was accomplished by resection of $2\frac{3}{4}$ inches from the distal metaphysis of the right femur.

CASE 5 (Case No. 11 Table I). R. B. was first observed at the age of 14 years. At 10 years of age it was first noted that the left leg was $1\frac{3}{4}$ inches shorter than the right. Roentgenographs revealed exostoses of the upper and lower femur and at both ends of the tibia.

Examination on admission at The University of Chicago Clinics revealed 3 inches of shortening of the left leg with increase in the diameter of the tibia at both ends as seen in Figure 6a. He limped conspicuously. Hard bony masses were felt on the anteromedial aspect of the distal end of the tibia and on the medial aspect of the distal end of the femur. Roentgenographs of the right knee showed narrowing of the shadows of the growth cartilages but the epiphyses were not united. Roentgenographs of the left upper tibia and lower femur showed a cartilaginous exostosis on the medial femoral metaphysis and four exostoses in the upper half of the tibia. The growth cartilages were ossified.

The right femur was shortened $2\frac{3}{4}$ inches. Figure 6b shows the appearance of the patient 3 months after operation. One year after operation his gait and appearance were normal. There was no increase in the residual length discrepancy of $\frac{3}{4}$ inch.

DISCUSSION

Data from the 15 cases are compiled in Table I. Cases 1 to 12 have been observed for periods of $1\frac{1}{2}$ to 9 years after operation. The remaining 3 patients have been operated on within 6 months and are under observation. The longest period of postoperative immobilization was $16\frac{1}{2}$ weeks in 1 case. The average period of immobilization was 10 weeks. Weight bearing with support was begun 6 to 8 weeks after operation. Postoperative infection was not encountered. In 1 instance separation of the bone ends occurred due to splitting of the intramedullary graft. In this case drill holes had not been made prior to the introduction of the transfixion screw. Reoperation was necessary.

Permanent quadriceps weakness was not observed in any of these cases. Quadriceps power returned to normal soon after removal of the plaster dressing and the duration and degree of weakness was no greater than that observed following similar periods of immobilization for other operations or injuries.

Circumferential elevation of periosteum from compact cortical bone of long bone diaphyses is a significant factor in producing avascular necrosis of the bone ends in fractures or operations. Healing of such a fracture or osteotomy is accompanied by gradual absorption of necrotic cortex and its subsequent replacement by living bone. Bridging of the ends by ossification of intermediary callus may be delayed for 6 months or longer and unless immobilization is prolonged incomplete ossification and nonunion may result. In the metaphysis where cortex is thinner and the blood supply is relatively greater extensive necrosis is less apt to occur. Metaphyseal fractures generally heal rapidly and experience with metaphyseal shortening of the femur reported here has shown that healing can be expected in approximately the time required for union of a fracture in the same location.

The lateral intermuscular approach to the distal end of the femur is simple and trauma to the quadriceps apparatus is minimal. Organization of hematomas and fibrosis of the vastus intermedius in midfemoral fractures and operations may leave permanent restric-

tion of flexion of the knee. Knee motion returned to normal 6 to 8 weeks after removal of the plaster dressing in all patients with metaphyseal shortening in this report.

Shortening the femur in the distal metaphysis minimizes the antagonistic action of hip and thigh musculature at the site of the osteotomy. The action of hip flexors and adductors may produce angulation in transverse diaphyseal osteotomies in the presence of both internal fixation and external immobilization with plaster. In osteotomies done above the condyles plaster immobilization is more effective and the adductor magnus and longus have relatively little effect on the osteotomy site. Tension of the gastrocnemius is reduced by immobilization of the knee in slight flexion.

Experience with these cases leads to the conclusion that supracondylar metaphyseal shortening of the femur is a relatively simple safe method of equalizing leg length. Operative trauma is minimal and the period of postoperative immobilization is short.

SUMMARY

1. The principles involved in leg length equalization procedures are discussed. Heredity, bone age, sex, stature, amount of length

discrepancy, condition of the tissues of the shorter limb, and associated disability or deformity are the chief factors to be considered.

2. The causes of leg length inequality in 15 cases are enumerated.

3. A method of shortening the femur in the distal metaphysis is described.

4. Five illustrative cases and end results in 15 cases of supracondylar shortening of the femur are presented.

5. Anatomical factors related to the choice of operative site in femoral shortening are discussed.

ANAL ILEOSTOMY WITH PRESERVATION OF THE SPHINCTER

A Proposed Operation in Patients Requiring Total Colectomy for Benign Lesions

MARK M RAVITCH MD F.A.C.S. and DAVID C SABISTON Jr., Baltimore Maryland

THE operation of total colectomy is most often performed for one of two conditions—multiple polypoid adenomatosis of the colon and chronic nonspecific ulcerative colitis.

Multiple polypoid adenomatosis of the colon or multiple polyposis has been well established to be a familial disease beginning with the report of Cripps. While it can make its appearance symptomatically as early as the age of 2 years (11) it is more often diagnosed in the second and third decades (9).

The therapeutic approach to multiple polypoid adenomatosis limited to the colon must be governed by the known facts concerning the condition—specifically the high incidence of malignancy developing in such polypoid adenomas and the high mortality reported. Various authors report an incidence of proved malignancy in such patients of from 26 per cent (15) to 62.5 per cent (2) with 35 to 40 per cent (6) as the most frequently reported figure. In 127 collected cases (6) 76 treated medically had a mortality of 56.5 per cent and 51 cases treated by any surgical means had a mortality of 35.1 per cent. The youngest patient diagnosed as having cancer was 12 years (7) the youngest dying of cancer was 15 years (11). Lockhart Mummery states that in all such patients cancer will develop if they survive. The usually recommended surgical treatment is resection of the involved bowel which often means a total colectomy and permanent ileostomy. A number of authors recommend fulguration of polyps in the area accessible to a sigmoidoscope and resection of the remainder

of the colon with ileosigmoidostomy. Lilienthal, Soper, Erdmann, Tom Jones (12) and Lockhart Mummery all have reported successful cases by this method. Stone and Rankin have also had such cases. However in a good number of such patients cancer has been reported to develop subsequently in the remaining rectal segment. We have had such an experience in this hospital.

CASE REPORT

F. K. No. 100268, a white girl of 16 years entered the Johns Hopkins Hospital September 29, 1936.

Fig. 1. Mesocolon and vessels ligated and divided. Terminal ileum mobilized by division of two arcuate vessels.

From the Surgical Hunterian Laboratory of the Department of Surgery, The Johns Hopkins University.
Presented before The Society of Clinical Surgery, Baltimore, Md., November 14, 1936.

Since this report was submitted the procedure described has been applied to a patient with ulcerative colitis. The result, 3 months after operation, is encouraging.

Fig. 1. A, Circular incision in mucocutaneous junction. B, gauze pack in rectum, submucosal dissection. C, dotted line indicates incision to be made through muscularis into peritoneal cavity.

complaining of abdominal cramps and diarrhea. Her father had died of cancer of the rectum at the age of 30. For 7 to 8 years she had bouts of diarrhea with cramps but without gross blood. She was admitted on the ninth day of a severe bout of diarrhea during the last 4 days of which generalized edema had developed.

Physical examination. She was extremely pale and generally edematous. There was clubbing of the fingers. Polyps were felt on digital rectal examination. The blood pressure was 80 systolic and 85 diastolic. The red blood cell count was 1,870,000, the hemoglobin 30 per cent. There were nucleated red blood cells in smears. The urine had a specific gravity of 1.00, albumin 70 grams per liter and on microscopic examination there were 1 to 3 red blood cells and 1 to 3 white blood cells per high powered field. The stool was liquid and the guaiac test for blood was positive. *Escherichia coli* was recovered from the urine culture. The phenolsulfonphthalein excretion was 34 per cent in 2 hours, the urea clearance 25 per cent of normal. The nonprotein nitrogen was 76 milligrams per 100 cubic centimeters. Barium enema showed countless polyps in the entire length of the colon. Sigmoidoscopy showed innumerable

small bleeding polyps of the entire rectum and lower sigmoid.

The urinary difficulties resolved on ammonium mandelate therapy. It was concluded that she had multiple polypoid adenomatosis with a coincident pyelonephritis. She was reported from this standpoint by Longcope and Whitehill.

Total colectomy was considered and abandoned in favor of preservation of the rectum and treatment of the distal segment with the cautery. A terminal ileostomy was performed December 1, 1936, and the colon subsequently resected in stages down to the rectosigmoid. All visible polyps were fulgurated proctoscopically on 9 occasions in November and December 1937 until no more were seen. On December 31, 1937, an ileosigmoidostomy was performed after resection of 9 centimeters more of the sigmoid. This specimen contained numerous polyps. She was well thereafter in the main and able to work. Proctoscopy showed "questionable sessile polyps" on September 3, 1938, fourteen months after the last fulguration. Rectal examination on a number of subsequent admissions for pyelonephritis was negative. February 9, 1945, she returned obstructed by a carcinoma of the rectum. February 2, 1945, an abdom-

Fig. 3 A Entire colon and several inches of terminal ileum delivered. Ileal serosa sutured to serosa of everted cuff of outer rectal coats remaining. B external sphincter sutured to ileum with interrupted sutures. C, ileum transected. D ileum tacked loosely to anal skin.

Inoperineal resection with permanent ileostomy was performed. There was a large adenocarcinoma in the upper end of the rectum. The remainder of the rectal mucosa was covered by innumerable benign polyps.

She died October 18, 1945 in a convalescent home of progressive cachexia presumably due to metastases—8 years after her rectal fulgurations.

Examination of the gross specimen with myriads of polyps carpeting the rectum indicates the small likelihood that any considerable number of such cases will be cured if a segment of involved bowel is left behind for topical treatment. The disease is preponderantly familial and a genetic predisposition to polyp formation should be expected to persist in this mucosa; however often it is fulgurated with malignant degeneration constantly threatening as long as the patient lives.

Fig. 4. Final appearance.

In short multiple polypoid adenomatosis of the colon is a symptomatically troublesome condition with dangerous malignant potentialities. The only safe treatment is permanent eradication of the abnormal epithelium—that

Fig. 5. Barium enema of dog B. 420 9 months after operation.

is bowel resection. When the entire colon is involved this means total colectomy. However, when operating in anticipation of but not in the presence of an established cancer, there is no need to remove the external sphincter.

Chronic nonspecific ulcerative colitis is not fundamentally a surgical disease. Its treatment should be medical, and undoubtedly there will be found a basically sounder treatment than diversion of the fecal stream, and occasional subsequent extirpation operations. At present, however, it can be accepted that ileostomy is often life-saving if undertaken sufficiently early (5, 17). That a certain percentage of patients will continue to have such troublesome symptoms after ileostomy in large bowel diseased beyond any hope of restitution to a functional state that colectomy will be required (1, 13). In these patients likewise, excepting those with multiple perineal and perianal fistulas, there is no need for sacrificing the sphincter ani.

In the experiments to be described the entire colon is resected, the sphincter preserved

and the ileum mobilized and sutured to the anus. The operation is offered for patients requiring total colectomy for nonmalignant conditions. From the standpoint of surgical therapeutic philosophy, this procedure has no relation to those designed to avoid colostomy in patients with cancer of the rectum and sigmoid.

OPERATIVE TECHNIQUE

Under intravenous nembutal anesthesia, the vessels and mesentery of the colon are divided and the terminal ileum is mobilized in a manner analogous to that employed for mobilization of the jejunum in esophagoplasty—division of one or more arcuate vessels and the attached mesentery—until the ileum will reach the perineum (Fig. 1). The intestine is then replaced and the abdomen closed. In the dog it is impractical to attempt a reconstruction of the pelvic peritoneum. The anus and rectum are then cleaned and the anus packed with dry gauze to support the mucosa in the dissection. The anal margin is held with Allis clips and a circular incision made in the mucocutaneous junction (Fig. 2A). Dissection is carried up submucosally, the developing cylinder of mucosa and submucosa being clamped to the gauze sponge (Fig. 2B). With traction the bowel almost peels out. When a flap 5 or 6 centimeters long has been developed, incision is carried through the outer rectal coats (Fig. 2C) into the peritoneal cavity. This frees the bowel which can be delivered through the intact sphincter. The entire colon and the mobilized ileum are delivered (Fig. 3A). The flap of outer coats of rectum is drawn down and everted so that it can be sutured to the ileum serosa to serosa. A continuous suture of No. 0000 catgut is employed to seal off the peritoneal cavity. This is followed (Fig. 3B) by interrupted sutures of the same material tacking the sphincter to the bowel. The ileum is then transected (Fig. 3C) and loosely sutured to the anal margin (Fig. 3D) with interrupted silk.

The final result is surprisingly normal in appearance (Fig. 4). An observer accustomed to sigmoidoscopic dogs passed a sigmoidoscope on one of these animals 8 days after operation, reported no lesion, and did not suspect the

true state of affairs. The dogs vary in their reaction to the operation. Good sphincter tone is regained. Defecation is apparently voluntary and more or less deliberate. The stools change from liquid to soft as time passes but the softness of the stools remains a problem which the dogs seem to solve by several small soft stools during the day and one copious stool at night. Dogs tolerate ileostomy poorly and some of those surviving have shown considerable perianal excoriation during the weeks immediately following operation gradually healing entirely. The x ray film (Fig 5) taken 5 months after operation in a dog who was operated upon 6 months before the time of this report, shows no dilatation of the ileum.

The dogs were operated upon in two groups. Neither received parenteral fluids before or after operation and no attempt was made in either to replace the fluids lost through the ileostomy. In the first group no antibiotics of any kind were given. Of 22 dogs 11 died of infection usually pelvic abscesses and peritonitis. In the second series the dogs received 0.5 gram of sulfasuxidine per kilogram per day for 4 days preceding operation (twice the usually calculated dose but given in 4 doses per day rather than 6) and 300 000 units of penicillin in oil and beeswax an hour before operation and another 300 000 units 24 hours later. None of the 6 dogs in the second group has shown any infection.

In man it may not be desirable to perform this operation regularly in one stage particularly for ulcerative colitis. However the feasibility of repairing the pelvic peritoneum and the possibility of pulling through a long stump of ileum to be divided later (we feared dogs would gnaw away such a stump) suggest to us that the operation should be safer in man than in the dog. We think that it may prove a feasible method of avoiding a permanent abdominal ileostomy in the patients requiring total colectomy for benign lesions.

TENDON TRANSFER OPERATION FOR IRREPARABLE PARALYSIS OF THE RADIAL NERVE

Long Term Follow-up of Patients

H. HEP AN YOUNG M.D., and GEORGE H. LOWE, Jr., M.D., Rochester Minnesota

AMONG the reconstructive operations brought to the foreground by World War II are the various types of tendon transfers for paralysis of the radial nerve. Most surgical reports on this procedure date back to World War I and shortly thereafter moreover there are few recorded follow-ups of more than a few months. The primary objective of this paper is to evaluate the results of tendon transfer operations for paralysis of the radial nerve as late as 26 years after operation.

Murphy in 1914 reported 2 cases of transfer of the flexor carpi radialis tendon to the extensor pollicis longus and extensors of the fingers for radial paralysis with excellent results. Murphy also indicated that he had done several operations of the same type previously. Byrne in June 1916 reported attaching the flexor carpi radialis to the extensors of the thumb and fingers. The tendon transfer in this case was performed 2 years after destruction of the radial nerve and the result was good.

Credit for the operation was given to Murphy. Sir Robert Jones in May 1916 wrote two excellent papers on tendon transplantation in which he discussed in detail operations for paralysis of the radial and median nerves. He indicated good results in 3 cases in which operation was performed by his associate McMurray. In the same year Henry described 1 case in which the flexor carpi radialis was pulled through the interosseous membrane and attached to the four finger extensors and the palmaris longus was inserted into the distal stump of the flexor carpi radialis. Weitz described methods and reported 2 cases. Schreiegg discussed technique in detail.

Between 1919 and 1922 tendon transfer operations for irreparable paralysis of the radial nerve were described and cases reported by many investigators. McMurray and Jones were the chief advocates of the following type of operation: (1) pronator teres into the two extensors carpi radiales; (2) flexor carpi ulnaris into either all four extensors of the fingers or in McMurray's method to the ulnar three; and (3) flexor carpi radialis into the abductor pollicis longus, the extensor pollicis brevis and in McMurray's cases also to the extensor of the index finger (Fig. 1). Jones also inserted the palmaris longus into the extensor pollicis longus. In this country Billington introduced an operation essentially the same as that described by Jones. Pennell in 12 cases prevented ventral flexion of the wrist by means of a fascial graft from the third and fourth metacarpals to the radius. The flexor carpi radialis tendon was passed through the pronator quadratus or interosseous membrane to the extensors of the fingers. The palmaris longus was then inserted into the extensor pollicis brevis. Starr had 50 per cent of excellent results and only 1 failure in 52 cases in which the pronator teres was inserted into the extensor carpi radialis longus and extensor carpi radialis brevis; the flexor carpi radialis into the four finger extensors and the palmaris longus into the extensors and abductor longus of the thumb. Stevenson in 50 cases reported good results at 12 weeks in an operation similar to that of Jones.

Intervening years have yielded few articles on this subject except discussions of methods found in textbooks dealing with the hand (4, 10) however in 4 cases with a maximal follow-up of 6 years good results were reported by Abbott in 1944 in an operation similar to that of McMurray along with arthrodesis of the wrist. Sudeck in 1943 described principles

From the Section on Orthopedic Surgery, Mayo Clinic, and the Section on Surgery, Mayo Foundation.
Read before the Clinical Orthopedic Society, October 12, 1946, Rochester, Minnesota.

to be observed. Recently Altman and Trott emphasized the value of numerous short incisions including a 2 inch (5 cm) transverse one on the dorsum of the wrist. In contrast to the right angle or U incision on the dorsum of the wrist there was never slough. In 16 cases good results were obtained with usable grip in all. Dorsiflexion of the wrist was limited to approximately 25 degrees and extension of the fingers was incomplete by 15 degrees. The tendon transfer was similar to the Jones operation. The follow up was brief since most of the patients had been wounded in World War II.

Zachary in April 1946 went into great detail concerning methods of quantitative measurement of results of tendon transfer operations for paralysis of the radial nerve. In the 57 cases of dorsal interosseous or radial nerve destruction exacting preoperative and postoperative studies of function were made. The paper should be studied by all future students in this field since quantitative methods will aid greatly in arriving at a conclusion as to the best types of tendon transfers. In 24 cases the flexor carpi ulnaris and flexor carpi radialis were transferred to the thumb and fingers (Jones's type of operation). Very poor extension of the fingers resulted in 6 of these cases in which there was no palmaris to help maintain some flexion at the wrist. Results in the other 18 cases with a palmaris longus present were somewhat better. In this series of 24 cases 50 per cent of ideal function based on degrees of motion and strength was calculated. In 29 instances the flexor carpi radialis was left intact and the flexor carpi ulnaris was passed to the finger extensors and in a few cases to the thumb extensors. In other instances the thumb extensors were activated by the brachioradialis by the palmaris longus or by an active wrist extensor. Zachary expressed the opinion that transfer of the pronator teres to the radial wrist extensors is of value and has little effect on ability to pronate the forearm. His conclusions would indicate that function is incomplete unless the wrist retains one flexor muscle, finger extension being only 21 per cent in the one instance and 97 per cent in the other. Ability to flex the wrist to neutral position was 40 per cent versus 100 per cent

Fig. 1. Anatomy of tendon transfer operation of the Jones type with the exception that the palmaris longus is left intact rather than inserted into the extensor pollicis longus.

and range of thumb extension was 16.5 per cent versus 69 per cent. The over all result was 50 ± 5 per cent versus 91 ± 0.4 per cent of ideal function. Each case is covered in detail in a chart.

METHODS

Twenty three patients who had destruction of the radial nerve and 5 who had loss of the dorsal interosseous nerve high in the forearm were studied. In all instances the site of injury of the nerve was explored and the nerve was found destroyed over a considerable distance or an anastomosis of the nerve ends was attempted with no sign of improvement for at least 1 year. All persons on whom the operation was performed through 1945 are included in the series despite complicating factors such as contractures and other nerve injury in some cases.

The follow up consisted of a form letter in which the patient was asked to compare various functions of the injured extremity with the corresponding functions of the normal side in terms of excellent, good, fair or poor. The general over all impression of the patient was asked along with the specific degree of func-

Fig. 2. Complete radial paralysis. Result 1 month after Jones type of operation. Not extent of wrist motion and extension of thumb but slightly incomplete extension of fingers.

tion as related to the extent of wrist motion finger extension thumb extension fist and strength of grasp. In addition nearly all patients were seen and examined at least 2 months or longer after the original operation. Photographs and in recent years, motion pictures were studied to aid in evaluating the results. In most instances in which all three methods of evaluation were used on one patient results agreed closely. Of necessity we are unable to evaluate our results in terms of degrees of motion or percentages because the personal examinations were done over a period of many years by many different observers. However by studying photographs impressions of the examining physicians and letters from the patients we have arrived at some valuable conclusions.

The tendons used and methods of transfer varied greatly. The Jones operation (Fig. 1) was performed in 10 cases the McMurray type in 4 and the Jones type without transfer

Fig. 3. a, above, Complete paralysis of the radial nerve, 9 weeks after operation. b, 6 weeks after operation. With excellent extension of fingers, thumb, and wrist.

of the pronator teres in 5. The technique in the remaining 9 cases varied greatly. The cutaneous incisions in most cases were of the extensive type including a J incision on the dorsum of the wrist. At the present time however small incisions at the sites of insertion of the flexor carpi ulnaris and the flexor carpi radialis, midway up the forearm over the body of each of these muscles and approximately in the midarm over the insertion of the pronator teres along with a somewhat longer incision just proximal to the dorsal carpal ligament are favored because of less tendency to scar and absence of necrosis of the skin.

RESULTS

The over all result (Figs. 2, 3, 4, and 5) for 28 cases was excellent in 10 cases, good in 13, fair in 5 and poor in none. When broken down into various operations the results were similar for each operation.

Six patients on whom operation had been performed between 11 and 26 years prior to their latest observation showed 3 excellent and 3 good results. This corresponded closely to the findings in those having transfers less than 1 year old; however patients on whom operation had been performed relatively recently were of course much less dexterous with their hands and fingers. In general it would appear that the ultimate outcome can be predicted by the findings a few months after operation.

The duration of complete muscular paralysis prior to operation varied from 2 months up to 23 years; in the latter case the result at 6 weeks was good. Strangely enough the results were not related to the duration of paralysis.

Only 1 patient showed what appeared to be an incomplete ability to flex the fingers because of the transferred tendons being inserted too near the dorsal carpal ligament. Several others had incomplete flexion of the fingers when the wrist was flexed; however from a practical standpoint fingers are rarely flexed with the wrist in ventral flexion.

Extension of the fingers was in all instances sufficient to permit normal function of the hand although in many cases the little finger did not extend as completely as the other three. In most of the cases there was inability to extend the fingers completely with the wrist in neutral position along with a tendency to extend the wrist somewhat on attempted complete extension of the fingers. This seemed to have little effect on the value of the hand and

Fig. 4. Same case as Figure 3. Twenty six years after operation. The patient reported essentially normal function of her hand.

was less frequent in patients years after operation.

Although many types of tendon transfers were done to bring about extension of the thumb the degree of motion was universally sufficient to provide excellent function.

Wrist motion and grasp were satisfactory in most cases. Some of the patients are now doing manual labor and using their hands with no favoritism. Among the patients mention was made of ability to use the hand with ease when typewriting, playing the piano, golfing

Fig. 5. a, Complete paralysis of the radial nerve, 1920. b, 16 months after operation extension is excellent. c, 16 months after operation patient is able to make a satisfactory fist. In 1946, 26 years after operation, he reported a satisfactory result.

welding and so forth. One patient was on full duty in the armed services. In no instance did a patient regret having had the operation.

CONCLUSIONS

Our series of 28 cases of irreparable destruction of the radial or dorsal interosseous nerve with a maximal period of follow up of 26 years reveals that tendon transfer operations for radial paralysis are very successful as a rule. The exact type of operation in our cases seemed to make little difference, however, by using the quantitative measurements of results as recommended by Zachary the value of the individual types of operation can be more carefully ascertained in the future. We are inclined to feel that it is better to have the wrist extensors somewhat stronger than the flexors since slight extension of the wrist is necessary to produce a strong grasp, although there is no question but that the fingers will extend more completely in the presence of fairly strong wrist flexors. We recommend leaving the flexor carpi radialis intact provided the palmaris longus or some other active muscle is available for extension of the thumb. Arthodesis of the wrist was not done in any case and we feel that it is usually not necessary. Numerous short cutaneous incisions are

preferred to extensive incisions with much undermining of cutaneous edges. As in all surgical procedures on the hand good hemostasis and a minimum of trauma to tissue are essential. The flexor carpi ulnaris must be attached to the finger extensors sufficiently far from the dorsal carpal ligament to prevent impingement and fixation when flexing the fingers.

RADICAL AMPUTATIONS OF THE EXTREMITIES IN THE TREATMENT OF CANCER

GEORGE T. PACK, M.D., HARRY E. EHRLICH, M.D., and FERNANDO de C. GENTIL, M.D.
New York, New York

AS our knowledge regarding the anatomic and clinical behavior of tumors of the soft somatic tissues increases and as our therapeutic experiences radiologic as well as surgical in the treatment of cancer of the limbs accumulate, certain definite concepts emerge. Throughout a period of twenty years there were over fifteen hundred cases of malignant tumors of the soft somatic tissues of the upper and lower extremities and the trunk, including over nine hundred cases of melanoma encountered on the Mixed Tumor Service of the Memorial Hospital. Perhaps the most significant realization garnered from this experience is that highly malignant connective tissue growths, melanomas, and selected cases of metastasizing epitheliomas must be dealt with radically *at the onset* if there is to be any hope for the patient's survival. It has been definitely proved that the prognosis becomes progressively poorer with an increasing number of recurrences following repeated local surgical excisions and conservative amputations, due to an obviously higher incidence of visceral metastasis.

Nowhere are these particular groups of cancers more favorably located for the application of radical surgical methods than on the limbs, especially when the regional lymph nodes have already been involved by the disease. Wide local excision of the primary tumor subsequently followed by a regional node dissection has proved to be an unsatisfactory surgical program in such a situation, for with this method the intervening lymphatic pathways are left intact. Only by excision and dissection in continuity can the primary lesion, in intervening lymphatic pathways, and the involved regional nodes be entirely removed.

From the Mixed Tumor Service, Memorial Hospital for Cancer and Allied Diseases. George T. Pack, Attending Surgeon, Harry E. Ehrlich, formerly Rockefeller Fellow in Cancer Research, Fernando de C. Gentil, Memorial Hospital Fellow.

Excision and dissection in continuity (4) is a term which we have employed to designate radical excision of the primary tumor intervening lymphatics and all regional lymph nodes by the same encompassing incisions. A wide removal of contiguous skin and even wider bloc of underlying fascia are included in the dissection. The surgical principle of excision and dissection in continuity is the same one on which the well established operations for breast and rectal cancer are based, namely, radical removal in continuity of the primary growth, intervening lymphatics, and the regional lymph nodes in one stage. If however the primary tumor is located too far from the first relay of lymph node metastasis (melanoma of the toe with metastasis to the inguinal lymph nodes) treatment by excision and dissection in continuity is not feasible. In such a case, only by exarticulation of the limb combined with excision of the regional lymph nodes can all gross limitations of the disease be widely removed—*interscapulothoracic amputation* (with or without supraclavicular neck dissection) for the upper extremity and *hip joint disarticulation* (with or without deep iliac dissection) or *sacroiliac disarticulation (hemi-pelvectomy)* for the lower extremity, depending on the clinical and anatomic factors present in the given case. The indications, surgical technique, and end results for all 3 of these radical amputations have previously been published by us (2, 5, 6).

The purpose of the present report is to analyze all of our cases of radical girdle amputations for malignant tumors in an effort to evaluate the usefulness of these operations for situations which have hitherto been considered practically hopeless. In addition, the value of radical amputation of the limbs in the palliative treatment of cancer will be discussed. This study is based upon 65 patients who were

Fig. 1. Surgical specimen from an interscapulothoracic amputation. Bilky fibrosarcoma presenting as axillary tumor. 7-year-old boy. Growth as densely adherent to postrior aspect of the scapula and head of humerus. This neoplasm could be removed only by radical girdle amputation. Such low grade spindle cell sarcomas of the fascial tendon aponeurotic type are non-metastasizing and the prognosis following *en bloc* surgical removal is excellent.

subjected to one of the three major amputations with or without a combined regional node dissection. All except 3 of these operations were performed on the Mixed Tumor Service of the Memorial Hospital from 1926 to 1946 without a single operative death.

INTERSCAPULOTHORACIC AMPUTATION

Interscapulothoracic amputation is an operation devised to remove the entire upper extremity, scapula, clavicle and their muscular attachments in one stage. The surgeon who performs such an extensive and mutilating procedure should have a clear conception of its indications and end results together with a comprehensive knowledge of the natural history of tumors.

Indications. The indications for this operation are malignant tumors of the upper limb which extend to or through the capsule of the shoulder joint or in its vicinity, extensive infiltrating cancers involving the deltoid, subscapular and pectoral muscles, particularly the unencapsulated myosarcomas, neurogenic sarcomas, liposarcomas, synoviomias, fibrosarcomas and spindle cell sarcomas of undetermined histogenesis, massive axillary neo-

Fig. 2. Melanoma of the skin of the shoulder. Large, kerated, infiltrating melanoma with demonstrably involved lymph nodes (proved by aspiration biopsy) in the lower neck and axilla. Excision and dissection in continuity would not be feasible in this case. Nothing less than an interscapulothoracic amputation combined with a lower (suprascavicular) neck dissection should be elected. The presence of this anatomic distribution in order to remove completely the gross limitations of the disease is clear. The prognosis following even such a radical surgical program is guarded in view of multiple node metastases to more than one regional lymphatic basin.

plasms, especially where they have become adherent to major blood vessels, the brachial plexus, shoulder joint, scapula or clavicle, sarcomas of the scapula and clavicle where there is invasion of the axilla or shoulder joint (Fig. 1).

In the treatment of melanoma of the skin of the upper limb with demonstrable involvement of the axillary lymph nodes (proved by aspiration biopsy) and in anatomically similar tumors, interscapulothoracic amputation is indicated whenever the practice of excision and dissection in continuity cannot be technically carried out (Fig. 2). Thus the principle of exarticulation of the limb combined with excision of the regional lymph nodes is applied in this way the axilla is encompassed

and excised rather than entered and dissected resulting in an *en masse* removal of the nodes an obviously desirable method of eradicating a regional lymphatic basin which contains melanoma. In the event that the supraclavicular lymph nodes are also involved by tumor a lower neck (supraclavicular) dissection can be included in the operation (Fig 3).

This radical amputation occasionally has a definite place in palliative therapy. When an extensive cancer involving the upper limb and shoulder girdle has become ulcerated and infected with the production of uncontrollable intractable pain it might be prudent in selected cases, to subject the patient to interscapulothoracic amputation even when distant metastasis has occurred. Elimination of sepsis and pain conversion to ambulation and partial activity can be accomplished in certain hopelessly advanced cases only by radical amputation.

In our series of 25 cases, interscapulothoracic amputation was performed for melanoma in 6 cases spindle cell sarcoma of undetermined histogenesis in 5 cases neurogenic sarcoma in 3 cases 2 cases each for rhabdomyosarcoma fibrosarcoma, synovioma and lymphangiosarcoma 1 case each for paraganglioma myosarcoma and epidermoid carcinoma. Five of the operations, or 20 per cent were performed for palliative purposes only. In 6 cases the procedure was combined with a lower (supraclavicular) neck dissection.

The oldest patient was 72 years and the youngest 10 years of age the average age was 34 years.

Operative considerations As previously mentioned graphic illustrations of the operation and a description of our standardized technique were published in 1942 (2) at which time we stated that the anterior or pectoral approach of Kocher was preferable to the classical Berger operation.

After the middle third of the clavicle has been resected the ligation of the subclavian vessels is postponed until the anterior incision is carried through the pectoral muscles into the axilla this part of the dissection is similar to the same phase of a radical mastectomy as the axillary artery and vein come immediately

Fig 3. Surgical specimen from an interscapulothoracic amputation combined with a lower (supraclavicular) neck dissection. Synovioma involving the flexor tendons of the wrist with metastasis to the lymph nodes of the axillary and supraclavicular spaces. The surgical principle of excarticulation of an extremity combined with excision of the regional lymph nodes is clearly indicated in this case. This type of tumor rivals that of melanoma in its malignant propensities. Operation performed under epidural anesthesia administered by one of us (F.C.G.) PT primary tumor M metastasis.

into view. With adequate exposure of the axilla and its contents the subclavian vessels are more readily located and the underlying artery mobilized and ligated without the hazard of injury to the overlying vein. Ligation of the subclavian vein is delayed as long as is feasible to allow the limb to drain itself of as much blood as possible. Division of the pectoral muscles gives an excellent exposure of the brachial plexus whose trunks are individually divided and ligated.

The linear incision over the clavicle is extended out to the acromion. The posterior flap is outlined by incising the skin along the vertebral border of the scapula uniting it with the anterior axillary incision along the lateral axillary border. The muscles along the vertebral border of the scapula are transected care being taken at this time to ligate the transverse cervical artery. The amputation is completed after the muscular attachments of the scapula have been severed. Most of the wounds are closed without drains.

Complications Healing is unusually good in

Fig. 4. Surgical specimen illustrating principle of excision of an extremity combined with excision of involved regional lymph nodes. This patient, 6 year old diabetic, developed subungual melanoma (melanotic whitlow) the size of match head on the right great toe with bulky metastasis to the femoral triangle. The surgical principle of "excision and dissection in continuity" could not be utilized in this case because the first relay of lymph node metastasis was too far removed from the primary lesion. Thus, the only method whereby the primary tumor, intervening lymphatics, and involved regional lymph nodes could be removed in their entirety was by amputation through the hip joint combined with deep iliac dissection. *PM*, primary melanoma; *M*, metastasis.

these cases. Skin grafting is resorted to in instances in which the size and the location of the tumor and the degree of skin involvement require a greater sacrifice of skin.

Shock is rarely encountered and then is only minimal when proper sustaining measures, such as the use of blood during the operative procedure, are employed.

If a tumor is fixed the pleural cavity might be entered with resultant pneumothorax, especially if the supraclavicular neck dissection is also carried out. This occurred in one of our cases; the pleural rent was repaired, the pneumothorax was appropriately aspirated, and the patient's convalescence was uneventful. Injury of the thoracic duct by a left interscapulothoracic amputation may conceivably occur, especially when combined with a lower neck dissection, although this complication was not encountered in the present series. Tributaries of the thoracic duct are ligated with fine wire or nylon and transected.

Prognosis following interscapulothoracic amputation. The usefulness and limitations of this or for that matter any surgical procedure can be determined accurately only by

careful examination of all patients, if possible, at frequent intervals. Thus, valuable data with regard to the subsequent clinical course are accumulated, the analysis of which is of paramount prognostic import. End-results are reliable only when computed on such a basis. No patient was lost to follow up examination in the present series of 25 interscapulothoracic amputations.

According to the histologic type of lesion for which this operation was employed, the prognosis was best for neurogenic sarcoma, fibrosarcoma, and spindle cell sarcoma of undetermined histogenesis, respectively. The least satisfactory results followed amputation for melanoma and synovium. Other histologic types were encountered much too infrequently usually singly so that a discussion on prognosis regarding these would not be in order.

In about 75 per cent of our cases, the primary lesion on the limb was also associated with metastasis to the axilla (proved by aspiration biopsy) and of the remaining cases, the primary tumor was located either in the axilla, or in the supraclavicular or infraclavicular spaces. The anatomic site of the tumor in those

patients operated on for curative purposes rather than for palliation, decidedly affected the eventual outcome for whenever the primary growth was situated in or about the axilla or shoulder the prognosis was much more favorable. The tendency for nonmetastasizing sarcomas of the fascial tendon type and of other low-grade (unclassified) spindle cell sarcomas to select the axillary and scapula regions so frequently explains the more favorable results which follow interscapulothoracic amputation for malignant tumors primarily located in the proximal end of the upper limb.

In radical amputation of the shoulder girdle whenever a supraclavicular or lower neck dissection was carried out during the same operative seance, the prognosis was not nearly as favorable as in the other clinical subgroups. Of 6 such cases 4 were performed for melanoma and 1 each for synovioma and squamous carcinoma. Three of these patients died of visceral metastasis. It must be remembered however that 2 of these amputations were performed for palliative purposes only which would ostensibly lower the net survival rate particularly for the combined operation (plus neck dissection) on the upper limb under discussion at the moment.

Interscapulothoracic amputation has a definite although limited use in the palliative therapy of cancer. In the present series of 25 cases, 5 were knowingly performed for palliative purposes only and of these 2 patients survived one year or more. Elimination of sepsis and pain and conversion of a bedridden frequently malodorous patient to comfort and ambulation may occasionally be accomplished by such radical surgical methods.

In addition to the histologic type of lesion the anatomic site, the performance of a superimposed partial neck dissection and the indication for operation, the last but perhaps the most important factor affecting the prognosis following interscapulothoracic amputation is the number of previous surgical procedures (local excision, conservative amputation, axillary dissection, scapulectomy) performed before radical operation is carried out. In 65 per cent of our cases, the patient had been subjected to at least one such surgical procedure in an attempt to eradicate the

Fig. 5. Surgical specimen from hip joint disarticulation. Endothelioma of the femur in a 9 year old girl treated with several courses of heavy irradiation elsewhere, with no regression of the tumor. On admission the patient was bedridden and suffering from intractable pain because of the ulcerated septic condition of the limb. Hip joint disarticulation was elected in spite of pulmonary metastases, purely as a palliative measure. This patient lived for 5 years following radical amputation, enjoying comfort and ambulation.

growth and 7 patients had undergone two or more operations before interscapulothoracic amputation was finally done. As can be seen in Table I the prognosis following this operation grows progressively worse with an increasing number of local recurrences due to a proportionately greater incidence of multiple regional node involvement and visceral metastases. This was particularly striking for melanoma, synovioma and highly malignant unclassified spindle cell sarcoma. Only when interscapulothoracic amputation will be utilized as the initial treatment provided that the indication is clear will the net survival rate following this operation be appreciably improved.

End results. In this reported series of 25 interscapulothoracic amputations for cancer, 13 patients were operated on during the past 4 years and in 5 cases the operation was performed as a palliative measure. Of the 20 curative operations 60 per cent of the patients

Fig. 6. Spindle cell sarcoma of the thigh with metastases to the inguinal lymph nodes. P T primary tumor M metastasis

were alive at the time of the analysis without evidence of recurrence or metastasis. The overall survival rate for the entire series is 54.2 per cent (Table I). The 5 year survival rate based on 11 cases in which patients were operated upon prior to June 1941 is 45.5 per cent.

HIP JOINT DISARTICULATION

As with cancers of the upper limb the management of malignant tumors of the lower extremity often entails amputation and of the various surgical techniques employed hip joint disarticulation in selected cases, combined with deep iliac dissection if necessary

gives promise of becoming most effective. The present discussion is based on a personal experience with 32 cases of amputations through the hip joint in 12 of which an *en bloc* excision of the iliac lymph nodes was carried out during the same operative seance. The oldest patient was 72 years and the youngest 3 years of age the average age was 39 years.

Indications Large malignant tumors of the soft parts of the middle and upper thigh which cannot be completely removed by wide excision and for which a high thigh amputation cannot assure an adequate margin are best treated by hip joint disarticulation. For malignant melanoma of the skin of the lower limb where involved inguinal and femoral lymph nodes are far removed from the primary tumor the principle of excision and dissection in continuity cannot be applied under such circumstances hip joint disarticulation combined with deep iliac dissection will accomplish effective removal of the primary tumor intervening lymphatics, and all surgically accessible lymph nodes (Figs. 4 and 6).

Malignant tumors of bone and periosteum which occur in the middle and upper femur and for which a high thigh amputation can not assure an adequate margin should be treated by hip joint disarticulation. Endothelial myeloma in such a location should be similarly treated if exhaustive studies have demonstrated absence of disease elsewhere.

This operation has a definite place in the palliative treatment of selected cases of cancer of the lower extremity. When the lower limb is the seat of a bulky ulcerated infected foul-smelling growth which involves the upper thigh (malignant lymphoma, Kaposi's multiple hemorrhagic sarcoma, primary malignant tumor with distant metastases, metastatic carcinoma) and the patient's general condition has not deteriorated too much amputation through the hip joint for palliation and comfort is occasionally justified (Fig. 5). If exarticulation of the hip joint is performed for either a primary operable malignant tumor or for palliative purposes only it is requisite that the neoplastic process should not extend to or through, the hip joint otherwise nothing less than amputation through the sacro-iliac joint (hemipelvectomy) will suffice.

In this series of 32 hip joint disarticulations 8 were performed for spindle cell sarcoma of undetermined histogenesis 7 for melanoma 5 for neurogenic sarcoma 4 for synovium 2 each for rhabdomyosarcoma chondrosarcoma and endothelioma 1 each for reticulum-cell sarcoma and osteogenic sarcoma Two of the amputations were performed as a palliative measure

Preoperative considerations Precautions should be taken to prevent shock The use of an Esmarch or elastic bandage wrapped around the limb to be amputated is invaluable in conserving circulating blood volume It should be carefully applied several hours before the operation is done An elastic bandage is definitely contraindicated however in cases of melanoma where it might possibly aid in the dissemination of tumor cells into the blood stream Constant administration of whole blood during the operative procedure is of course an essential feature in the prevention of shock which may occur following massive or uncontrollable hemorrhage although this was not once encountered in any of our cases

In the event that the tumor is ulcerated and infected daily local treatment, consisting of gentle débridement cleansing and anti septic sprays and frequently applied wet dressings and chemotherapy is of distinct value in reducing the septic condition of the limb

A Foley urethral catheter is inserted into the urinary bladder before the patient is taken to the operating room

Operative considerations Our standardized technique has recently been graphically illustrated (5) and will not be repeated in detail

An anterior racquet incision is used The neuromuscular bundle in Scarpa's triangle is cleared and the femoral artery is ligated and divided (*above the profunda femoris*) as is the femoral nerve Thick skin flaps are developed after which all anterior muscle groups are transected as near to their insertion as possible It is advisable to cut the sartorius and rectus femoris rather low so that they may be later used to cover the acetabulum The femoral vein is then ligated and divided thus completing the anterior dissection

Adduction and internal rotation of the limb bring the greater trochanter into view so that

the muscles which insert into it may be severed after which the muscles of the gluteal group are cut The capsule of the hip joint is incised and by further vigorous adduction of the limb the head of the femur is actually forced out of its acetabulum (surgical dislocation) After cutting the round ligament the specimen is left attached to the patient only by a posterior pedicle consisting of the hamstring muscles and sciatic nerves which are severed thus completing the disarticulation

HIP JOINT DISARTICULATION WITH DEEP ILIAC DISSECTION

Whenever there is an indication to combine deep iliac dissection for the purpose of removing iliac and retroperitoneal lymph nodes with disarticulation of the hip joint, the technique must necessarily be modified The method of radical groin dissection as performed on the Mixed Tumor Service of the Memorial Hospital (3) is employed but is altered by omitting the dissection of the upper thigh and Hunter's canal The apex of the incision is placed somewhat higher and more medially on the anterior abdominal wall and thin anterior and medial skin flaps are developed Dissection is carried from above downward denuding the lower anterior abdominal wall inguinal region and femoral vessels of fascia, fat and lymphatic tissue *en bloc* By splitting the inguinal ligament and retracting the peritoneum and urinary bladder the retroperitoneal space is exposed widely The chain of lymph nodes and areolar tissue along the iliac vessels are removed *en masse* including those overlying the obturator foramen If necessary the anterior abdominal wall may be incised vertically upward, exposing the retroperitoneal space and its contents well beyond the aortic bifurcation On completion of this deep iliac dissection the common femoral artery is ligated and divided *above the profunda femoris* and the operation of hip joint disarticulation is carried out in the usual manner

The wound should be appropriately drained Because of the extensive skin flaps which are developed when a regional node dissection accompanies the amputation it is essential that a bulky pressure dressing be applied firm enough to prevent pocketing of serum but not

too firm otherwise necrosis of the flaps will occur.

Complications. In general the course following hip joint disarticulation is relatively smooth and uneventful. When not combined with deep iliac dissection the wound heals *per primam*. The utilization of extensive skin flaps when the amputation is combined with deep iliac dissection invariably produces skin necrosis along the wound margins, frequently resulting in infections. Lymphorrhea and pocketing of serum beneath the flaps also encourage infections and contribute to poor wound healing.

Aspiration of accumulated serum judiciously applied pressure dressings adequate postoperative penicillin therapy and wide excision of irradiated skin are essential features in the prevention of infection and promotion of satisfactory wound healing following the combined operation.

Prosthesis. Because of the absence of a stump the fitting of a prosthesis is a difficult matter following amputation through the hip joint although additional iliac dissection does not add materially to this problem. We have employed a prosthesis for these cases consist-

ing of a leather pelvic support to which the artificial limb is attached. This prosthesis has a double joint action and weighs 10 pounds. (5) It is worn no more than 1 or 2 hours daily for the first few months as the patients find it quite tiring.

Prognosis following amputation through the hip joint. As pointed out in discussing the radical operation on the upper extremity the prognosis following amputation through the hip joint will depend upon the anatomic type of tumor and its extent, the presence of visceral metastasis, and the number and variety of previous surgical procedures (local excision, local excision followed by groin dissection, conservative amputation). In general, the prognosis following hip joint disarticulation is about the same as that following inter-scapulothoracic amputation. In retrospect, however, in view of our past experience with radical amputations 5 of the patients subjected to amputation through the hip joint (2 for palliation) would at present be treated by hemipelvectomy. A clearer definition of the indications for *disarticulation* leads will eventually improve the cure rate for both operations.

The most favorable results followed operation for neurogenic sarcoma and low grade (unclassified) spindle cell sarcoma. The least favorable outcome was encountered in melanoma and synovialoma. Again the majority of our patients were not ideally operable cases because of bulky metastasis to the inguinal lymph nodes with prior attempts at groin dissection. A more important factor to influence unfavorably the prognosis following radical amputation of the lower extremity is a high incidence of repeated, usually inadequate, surgical interventions followed by recurrences, before disarticulation was finally done. Over four fifths of the patients in the present series were subjected to some type of surgical procedure prior to radical amputation. In 21 cases local surgical excision was performed at least once and in 10 cases 2 or more limited excisions had been performed. Three patients had undergone previous conservative amputation and in 4 cases groin dissection had been carried out. Only when radical amputation (disarticulation) will be employed

as the initial mode of therapy in previously untreated cases provided the indication is clear will we be able accurately and finally to evaluate the usefulness and limitations of such surgical practice in the management of selected cases of cancer of the extremities

End results In the Memorial Hospital Series (Mixed Tumor Service) of 32 cases of hip joint disarticulation 4 were performed for palliative purposes only. Of the 28 curative operations 42.9 per cent of these patients are alive, as of June, 1946 with no evidence of recurrence or metastasis. Only 1 patient in this series of 32 cases was lost to periodic observation after a follow up interval of 2 years.

Almost three-fourths of the patients in this group were operated on during the past 4 years. The over all net survival rate is 38.7 per cent (Table II). The 5 year survival rate is 33.3 per cent.

SACROILIAC DISARTICULATION (HEMIPELVECTOMY)

Since 1944 we have performed the operation of sacroiliac disarticulation¹ in which the entire lower extremity corresponding buttock and innominate bone are removed in one stage, on 8 occasions. One of these operations was performed by the senior author at another hospital. The standardized technique as employed by us has been illustrated elsewhere⁽⁶⁾ and is based on our modification of the surgical procedure first performed by Hogarth Lingle in 1916. The fact that the first operation of this kind was undertaken so late in the history of the Mixed Tumor Service may be explained by the many years which have been required to exploit more conservative therapeutic procedures radiologic as well as surgical for the treatment of malignant tumors of the soft somatic tissues before resorting to an extensive deforming operation in addition to our present more comprehensive knowledge concerning the clinical behavior of tumors of the soft parts.

Indications Sacroiliac disarticulation is indicated for primary malignant osseous and periosteal tumors of the upper femur where the

Fig. 7 Surgical specimen from amputation through the sacroiliac joint (hemipelvectomy). Massive myxoliposarcoma (specimen bisected) involving the upper thigh and groin and extending over the anterior superior iliac spine. Dissection of the hindquarter revealed the tumor to be centered in the iliopsoas muscle. Bulky malignant infiltrating tumors of the pelvic parietes are occasionally amenable to surgical extirpation by disarticulation of the innominate bone.

growth has extended to or through the hip joint and for similar neoplasms of the innominate bone. Primary bulky malignant tumors of the soft somatic tissues of the upper thigh (involving the hip joint or extending through the obturator foramen) groin, buttock, pelvic parietes and iliac region are best treated by amputation through the sacroiliac joint (Fig. 7).

Massive osteochondromas of the innominate bone and massive plexiform neurofibromas involving the upper thigh, groin and hip joint or the buttock and pelvic parietes are best treated by exarticulation of the lower limb through the sacroiliac joint if the tumors contain atypical areas histologically and if they cannot be adequately removed by wide local excision or some other type of conservative operation.

This radical operation occasionally has a definite place in the palliative therapy of cancer. Even in the presence of hopeless extension or distant metastasis fungating ulcerated tumors of the upper thigh, groin and buttock may be removed in selected cases by sacroiliac disarticulation with gratifying results provided the patient's general condition has not deteriorated too much.

The operations which are here reported

¹Other terms which have been employed for this operation are hemipelvectomy, disarticulation of the innominate bone, hindquarter operation, interpelvical amputation, interiliacropubic amputation, transiliac operation, and interinnominatebone amputation.

were performed for chondrosarcoma (2 cases) myxoliposarcoma (2 cases) neurogenic sarcoma Kaposi's multiple hemorrhagic sarcoma perosteal fibrosarcoma, and extraosseous osteogenic sarcoma. Two operations were performed for palliation. It is, of course mandatory that a histologic diagnosis be established by aspiration or incisional biopsy before radical amputation or any other surgical or non surgical program for that matter is planned.

Operative considerations The preoperative considerations and precautions which were discussed for hip joint disarticulation are also applicable for cases of sacroiliac disarticulation. Inhalation anesthesia was employed for all cases. In any surgical procedure where a marked drop in blood pressure might occur spinal anesthesia should not be elected. Rotation of the patient which is necessary for the posterior dissection definitely interferes with the technique of continuous spinal anesthesia. In addition the psychic trauma necessarily induced by a mutilating operation is obviously lessened with the patient asleep.

As already mentioned a detailed description of all steps of this operation as performed by us has been published elsewhere (6) and

will not be repeated in the present report. Certain salient features of the technique, however will be reviewed.

1. An anterior racquet incision is employed.
2. In the first few cases, we divided and ligated the external iliac artery as early in the operation as possible but ligation of the vein was delayed to allow the extremity to drain itself of as much blood as possible. We soon found that ligation of the common iliac artery permitted a relatively bloodless operation. In one instance however necrosis of the posterior flap followed ligation of the common iliac artery but this complication can be prevented by using a T incision with the straight crossbar along the inguinal region and the vertical incision resulting from a wide V extension of the center segment of the longer posterior flap.
3. By severing the pubic insertion of the rectus abdominis and dividing the inguinal ligament the anterior abdominal wall is actually detached from the bony pelvis.

4. By retracting the peritoneum its contents, and the urinary bladder the iliac fossa is widely exposed. The ureter, peritoneum, intestines and urinary bladder must not be injured. The spermatic cord is preserved.

5. The symphysis pubis is easily divided with a Gigli saw but it should be clearly skeletonized otherwise the pubic arch will instead be cut through.

6. The external iliac vein is ligated and divided just prior to exposure of the sacroiliac joint. Disarticulation of the joint is performed during the anterior phase of the dissection, using a chisel.

7. The posterior dissection is left for last, at which time the amputation is completed by severing the gluteal muscles, major ligaments of the sacrum and the great nerve trunks of the lumbar and sacral plexus.

With this technique all the major maneuvers of the operation are performed through an anterior approach providing for ample exposure and easy access to vital structures in the pelvis.

Postoperative complications Abdominal distention is a frequent postoperative complication. If a Levine tube is placed in the stomach as soon as the patient has reacted from the anesthetic and constant suction is applied for

48 to 72 hours, serious abdominal distention can be avoided. Obviously large amounts of plasma should be given during this time to combat an inevitable electrolyte imbalance and hypoproteinemia.

Paralysis of the urinary bladder occurs often but is only temporary lasting 4 to 7 days. Continuous tidal bladder drainage is not only beneficial for an atonic bladder but prevents soiling of the dressing during the first post operative week.

Anemia is a constant postoperative manifestation and does not respond to iron liver extract or blood transfusions. We have found evidence in our cases, of compensatory marrow hyperplasia. It is not unlikely therefore, that removal of an entire lower extremity and innominate bone deprives the hemopoietic system of sufficient bone marrow so as to produce this normocytic normochromic anemia which is only temporary lasting about 3 weeks.

Fecal incontinence and abdominal herniation do not occur following this operation although loss of libido is experienced rather frequently.

A prosthesis has never been devised for these cases. The patients learn to sit on the opposite ischial tuberosity and manage to use crutches satisfactorily after about 3 weeks of practice.

One of our patients, a 26 year old white female who was subjected to hemipelvectomy in March 1945 for a neurogenic sarcoma of the thigh and pelvic parietes married and became pregnant 1 year after operation and expects to give birth within a few months. No obstetrical difficulties should be anticipated in hemipelvectomy women. Judin's patient conceived and gave birth spontaneously to a healthy infant following sacroiliac disarticulation.

Prognosis and end results following hemipelvectomy. The neoplasms of the soft parts which carry the best prognosis following this operation are neurogenic sarcoma and non metastasizing low grade spindle cell sarcoma of the fascial tendon type. Of the bone tumors chondrosarcoma offers the most favorable prognosis.

In the present series of 8 sacroiliac disarticulations 2 were performed for palliation

TABLE IV -- EXARTICULATION OF THE EXTREMITIES FOR MALIGNANT TUMORS MEMORIAL HOSPITAL SERIES--MIXED TUMOR SERVICE SUMMARY OF END-RESULTS 1926 TO 1946

Over-all net survival rate			54.1 per cent.

both of these patients died—one 12 months and the other 15 months after the operation. Of the 6 curative cases 1 patient died suddenly 7 months after the operation at which time there was no clinical evidence of recurrence or metastasis. The remaining 5 patients are alive and free from disease at the time of this analysis.

The net survival rate for the entire series of hemipelvectomy patients in all stages of disease was 71.4 per cent (Table III). Obviously the 5 year cure rate cannot as yet be computed for this group as the operation was not employed by us until the year 1944.

SUMMARY AND CONCLUSIONS

Sixty five patients were subjected to one of three major amputations (interscapulothoracic amputation hip joint disarticulation sacroiliac disarticulation) for neoplastic disease on or about the extremities. These operations need not be hazardous. There were no operative deaths in this series.

The indications operative technique and postoperative complications for these three surgical procedures are discussed with special emphasis on the prevention and treatment of complications specific for cases of amputation through the sacroiliac joint.

The surgical principle of exarticulation of an extremity with excision of the involved regional lymph nodes in one stage for selected cases of melanoma and clinically similar tumors is presented and illustrated by 6 cases of interscapulothoracic amputation combined with a lower (supraclavicular) neck dissection and 12 cases of hip joint disarticulation combined with a deep iliac dissection.

The value of these surgical procedures in the palliative therapy of cancer is shown. Nine of the amputations in the present series were performed for palliative purposes only.

Interscapulothoracic amputation and hip joint disarticulation serve a definite and distinctly useful rôle in the treatment of selected cases of cancer of the extremities. With regard to amputation through the sacroiliac joint (hemipelvectomy) our cases are too few and too recent as yet on which to base an accurate and final evaluation of the operation. The accumulated evidence indicates that sacroiliac disarticulation will prove to be a valuable surgical procedure in the treatment of extensive cancers of the lower limbs, groin, buttock, innominate bone and pelvic parietes.

In this series of 65 cases only 1 was lost to follow up examination 2 years after operation. The 5 year survival rate following interscapulothoracic amputation is 45.5 per cent, and for hip joint disarticulation 33.3 per cent. The net survival rate for cases of sacroiliac disarticulation is 71.4 per cent (Table IV).

EXTENSIVE COMBINED THORACOLUMBAR SYMPATHECTOMY IN HYPERTENSION

JAMES L. POPPEN M.D., F.A.C.S. Boston Massachusetts

IN many instances prolonged lowering of the blood pressure occurs in well selected cases following extensive thoracolumbar sympathectomy. It has been my experience that the fall in blood pressure with the patient in the horizontal position does not depend entirely on the extensiveness of the sympathectomy. The postural effect on the blood pressure however depends on the completeness of denervation of the splanchnic area. Therefore to obtain effects immediately or for a period of 3 or 4 months it is not necessary to deviate from the technique of either the supradiaphragmatic approach used by Peet or the subdiaphragmatic approach employed by Adson. Smithwick demonstrated to his satisfaction that extensive removal of the sympathetic nervous system was necessary to maintain a prolonged lowering of blood pressure. In 1938 he devised an operation permitting him to combine the supradiaphragmatic approach of Peet with the subdiaphragmatic operation of Adson by the removal of the twelfth rib and incising the diaphragm thus allowing exposure for a more complete splanchnic denervation. Grimson in 1941 described a technique for complete thoracic and partial to total lumbar sympathectomy.

In my experiences since 1934 with the surgical treatment of hypertension the technique advised and so adequately demonstrated by Peet was first employed. Later the subdiaphragmatic approach was used as advocated and devised by Craig and Adson. In 1938 the latter technique was combined with a unilateral nephro-omentopexy. Since 1940 by a gradual evolution the thoracolumbar sympathectomy has become more and more extensive (5).

It has been shown by many investigators¹ that regeneration of the sympathetic nervous

system is most difficult to retard. That this is true is illustrated by special tests on 2 patients whose drop in blood pressure was considered good for a period of 2 years following operation. The preoperative blood pressure levels and the complaints of severe headaches returned however after the 2 years had elapsed. These patients were subjected to further removal of the sympathetic nervous system with good results. It has been my experience that if an immediate drop in blood pressure does not occur within a reasonable length of time following operation more extensive removal of the sympathetic nervous system will not be beneficial. Therefore subjecting hypertensive patients to more extensive sympathetic denervation is justified only in patients who have had relief of symptoms for 6 months or more whose previous complaints then returned and the blood pressure became elevated.²

Since neither the mortality nor the morbidity is increased by the technique that is employed at the present time the added assurance that a more complete denervation has been accomplished makes the procedure a justifiable one.

The operation is performed in two stages at approximately 10 day intervals. The position of the patient during operation is of the utmost importance in facilitating the procedure. A lateral semiprone position is used (Fig. 1) with the thoracic spine flexed forward to as great a degree as possible. Flexion aids in making the upper dorsal ganglia more accessible. Either a combination of high spinal anesthesia reaching up to the fourth thoracic level and a light intravenous pentothal anesthesia, or the combination of pentothal curare and nitrous oxide is used. It is absolutely necessary to have adequate oxygenation throughout the operation.

Poppen, J. L. The surgical treatment of essential hypertension (In press.)

From the Department of Neurosurgery, The Lahey Clinic.
Dr. Kurt Richter of Johns Hopkins Hospital has studied many of our patients at varying intervals after operation from the standpoint of skin resistance.

Fig. Photograph showing the lateral semiprone position of the patient and the site of previous incision.

The incision is made paravertebrally over the thickest portion of the long muscles of the back at the line of cleavage of the longissimus dorsi and iliocostalis dorsi muscles. It extends from the level of the seventh rib curving very slightly anteriorly to the distal portion of the twelfth rib (Fig. 2). The longissimus dorsi and iliocostalis dorsi muscles are separated over the medial portion of the eleventh rib as well as over the seventh or eighth rib. The seventh rib is removed if the dorsal spine cannot be flexed, as is the case in a few straight backed individuals. If the dorsal spine can be flexed readily experience has demonstrated that the fourth dorsal ganglion can be removed more easily through the eighth than through the seventh rib. The medial portions of the eleventh and the seventh or eighth ribs are then removed for a distance of approximately 4 centimeters from the transverse process care being taken that the rib is not removed farther laterally than the width of the iliocostalis and longissimus dorsi muscles so as to prevent deformity. Removal of as much of the rib vertebrally as possible allows more adequate exposure.

Considerable care should be taken to enter the proper line of cleavage between the parietal pleura and endothoracic fascia. When the line of cleavage has been established it can be followed medially with a semisharp Hedblom periosteal elevator to the anterolateral border

of the bodies of the vertebrae where the greater splanchnic nerve lies. The index finger may then be inserted into the space and the line of cleavage followed cephalad and caudad through the openings of the seventh or eighth and the eleventh ribs. Caution must be exercised at this point that the palmar surface of the index finger is kept firmly against the endothoracic fascia rather than against the parietal pleura as the line of cleavage is being followed to prevent rupture of the parietal pleura. It is needless to emphasize that opening of the pleura should be avoided if at all possible since a relatively quiet anatomical dissection is immediately transformed into a more difficult and somewhat noisy procedure if the pleura is opened. Even though considerable care has been used the pleura has been opened in 5 per cent of operations. The mere opening of the pleura may not be disastrous or cause more than relatively minor difficulties at the time the operation is performed. If by chance a post-operative infection should take place however one must necessarily deal with an empyema. This certainly is adequate reason to avoid studiously opening the pleura. Anesthesia can be of great assistance in preventing injury to the pleura by the control of the depth and rate of the respirations.

After the pleura has been separated paravertebrally cephalad to the level of the fourth thoracic ganglion and caudad to the attach-

Fig. 2. The incision is outlined in the insert. The approach to the thoracic chain with its branches is made by removal of segments of the seventh or eighth and eleventh ribs by separating the iliocostalis and longissimus dorsi muscles. The long deep muscles of the back are retracted toward the spinous processes below the twelfth rib, thus allowing the retroperitoneal space to be entered by incising the transversalis fascia.

ment of the diaphragm the greater splanchnic nerve is mobilized along its entire length. The greater splanchnic nerve is mobilized first because it is in a relatively avascular bed. With the patient in the semiprone position, if slight oozing should take place at the time the gan-

glia are mobilized and their respective rami divided, blood gravitates toward the mediastinum. If the greater splanchnic nerve were separated after the ganglia had been mobilized, possibly it would be obscured by blood-stained tissue.

Fig. 3 The insert demonstrates the separation of the ganglion from the intercostal vessels before the rami communicantes are divided. The drawing allows visualization of the entire splanchnic distribution from the inside and its relationship to the apertures through which the removal is accomplished.

Great care is taken in mobilizing the delicate nerve fibers that make up the greater splanchnic nerve from the individual ganglia (Fig. 3). It is surprising to note the difference in the size of the individual ganglia as well as the fact that some of the ganglia do not have individual fibers leading from them to the greater splanchnic nerve (Fig. 4). In a few instances connecting fibers lead directly from

the thoracic trunk to greater splanchnic nerve (Fig. 5a). The main trunk of the splanchnic nerve usually arises from fifth or sixth ganglion (Fig. 6) but in several patients it has arisen as a separate trunk from as high as the fourth ganglion (Fig. 7). The nerve itself may have one to several ganglia or may have none.

After the fourth thoracic ganglion has been mobilized the trunk is divided above it. The

Fig. 4.

Fig. 5.

Fig. 6.

Fig. 4. Photograph of an actual specimen placed on a schematic drawing of the corresponding thoracic and lumbar vertebrae. Demonstrates the variation in the size of the ganglia as well as the fact that each ganglion may not have an individual connection with the greater splanchnic.

Fig. 5. Photographs of the actual surgical specimens showing the greater splanchnic arising from the thoracic

ganglia by individual fibers. *a*, Demonstrates how two ganglia in this instance the ninth and tenth, send joint fibers to the greater splanchnic as well as a separate branch from the thoracic trunk between them.

Fig. 6. Demonstrates the splanchnic arising from the fifth thoracic ganglion, *a* and from the sixth thoracic ganglion *b*.

entire mobilized upper sympathetic trunk and its branches are then pulled down through the aperture made by the removal of the eleventh rib care being taken that the entire system is kept in continuity so that there can be no question or possibility of leaving any ganglia or any fibers that lead to the thoracic aorta. Care must be taken that the thoracic ganglia are separated from the intercostal nerve and artery before dividing the ramus to avoid unnecessary bleeding (Fig. 3 insert). All bleeding even from a larger intercostal artery can readily be controlled by the electro-surgical unit.

It has been my experience that the dissection is less difficult if the thoracic trunk is not divided until the desired number of ganglia that are to be removed have been mobilized

After the thoracic ganglia and trunk as well as the splanchnic nerve have been completely mobilized in continuity to the diaphragm the iliocostalis and longissimus dorsi muscles which are called the sacrospinalis muscle at the level of the twelfth rib are retracted medially toward the spine. This permits the lumbodorsal fascia as well as the transversalis fascia to be incised care being taken during the dissection that the iliohypogastric nerve is not injured. The retroperitoneal space is then entered and the soft tissues retracted anteriorly. The greater splanchnic nerve can be readily identified as it emerges through the diaphragm usually through a hiatus of its own (Fig. 3) although it may emerge through the aortic hiatus. The greater and lesser

Fig. 7 Demonstrates separate ganglia in the greater splanchnic also the greater splanchnic arising from the fourth thoracic ganglion

splanchnic nerves emerge through the same aperture in many patients however in others they emerge through a separate aperture in the diaphragm. The greater and lesser splanchnic nerves are then detached from the celiac ganglion. The lesser splanchnic nerve usually has fibers entering the celiac ganglion and smaller fibers entering the aorticorenal ganglion (Fig. 3). In the female the third lumbar ganglion is mobilized and the trunk immediately beneath it divided. In many instances fibers may be seen extending from the third lumbar to the aorticorenal ganglion or directly to the abdominal aorta. In other patients none may be found. The second lumbar ganglion always has a few fibers leading to the aorticorenal ganglion the first usually having a fairly sizable trunk or at times several small strands of nerve leading to the aorticorenal ganglion (Fig. 8b). The rami of the second lumbar ganglion are then divided the crux of

Fig. 8 The more common appearance of the thoracic and lumbar ganglia with their splanchnic branches also the aorticorenal from the first and second lumbar

the diaphragm usually covers a part of the first lumbar ganglion. With the distal end of the lumbar trunk kept under slight tension, the crux of the diaphragm is incised and the first lumbar ganglion readily exposed and its rami divided. The incision through the crux of the diaphragm is then increased for a distance of several millimeters so that the aperture in the diaphragm is of sufficient size to permit the ganglia to be pulled through it from above. The mobilized cephalad end of the thoracic trunk and the splanchnic nerve are then grasped with forceps and by gentle traction the subdiaphragmatic portion of the greater and lesser splanchnic nerves as well as the lumbar trunk can readily be brought through the diaphragmatic aperture. In this manner the entire system is kept in continuity and there can be no question as to the completeness of the procedure.

Photographs are taken of the specimen so that they may be used for future reference. If for instance unusual areas of excessive perspiration develop in a supposedly denervated

area, one can refer to the photograph and determine whether or not the ganglia involved were actually removed. In this manner one can determine, also, at a later date how much regeneration actually takes place in these individuals.

That the operation in competent hands is not associated with great danger is indicated by the fact that one postoperative death has occurred in 250 patients with essential hypertension. This patient died from a coronary thrombosis on the second day following the second stage operation. Superficial wound infections were encountered in 4 cases which were readily controlled by immediate drainage and removal of the black silk sutures. In none of these cases of infection has the thoracic cavity been involved. In several cases slight pleural effusion has developed and in only 3 instances was aspiration thought necessary in the remaining cases the effusion subsided within a few days without aspiration. Unfortu-

nately severe postoperative discomfort which was directly due to mechanical intercostal neuralgia occurred in a considerable number of these patients and lasted from several days to several weeks.

SUMMARY

A technique for extensive thoracolumbar sympathectomy is described which allows adequate exposure for removal of the sympathetic system from the fourth thoracic to the third lumbar ganglia, inclusive.

THE IMPORTANCE OF BLOOD IN PREOPERATIVE AND POSTOPERATIVE TREATMENT

IN order to carry on the important functions of the blood and to meet emergencies, such as sudden loss of blood, trauma and major operations, an adequate volume of circulating blood must be maintained and enough hemoglobin must be maintained in the erythrocytes to supply oxygen to the tissues. The effects of sudden hemorrhages such as occur in peptic ulcers, placenta previa, ruptured ectopic pregnancies, ruptured uteri and pulmonary tuberculosis may be offset by transfusions of blood. The use of transfusions of blood before operation to minimize or to prevent shock in such cases and to prepare patients who have jaundice or hemorrhagic diseases is generally accepted. In the obstetrical emergencies Rh negative blood should be given when the Rh type has not been determined previously.

It has been found that transfusions of blood will decrease coagulation time. Since transfusion of 100 cubic centimeters of fresh blood usually is enough to produce a hemostatic effect, a preoperative transfusion may make surgical procedures possible in conditions such as jaundice or certain blood dyscrasias in which they would otherwise have been impossible.

Usually a patient with acute or chronic anemia has a marked decrease in blood volume in which case fewer erythrocytes are present to carry oxygen and carbon dioxide and because of the necessity for increased cardiac output the heart may be strained. A patient who has either acute or chronic anemia may reach the stage of air hunger as a result of the anemia. *Anemia may result from slow loss of blood in conditions such as menorrhagia, slowly bleeding ulcer and rectal disorders (hemorrhoids or neoplasms).* If the patient with this type of anemia undergoes operation, trauma or further loss of blood, irrespective of the type of anesthesia, shock or permanent cerebral damage may ensue because the oxygen supply to the brain is insufficient.

When a patient is anemic, the choice of the anesthetic agent for an operative procedure may be difficult. For example, some operative procedures are best done with the patient under spinal anesthesia. However if the concentration of hemoglobin is less than 50 per cent, use of this anesthetic procedure is definitely contraindicated.

In the postoperative period certain additional conditions may be present in which blood transfusions may prove of value. Favorable results of transfusions in treatment of certain infectious diseases have been reported.

The purpose is to add such antibacterial agents as natural antibodies leucocytes and complement to the blood of the recipient. Immunotransfusions may have even more value.

A patient who is doing well in many respects but does not eat, seems tired and listless and has little strength frequently responds well to one or more transfusions. The exact reason for this is unknown. The hemopoietic power may have become depleted and not enough blood cells are produced for the patient to carry on a normal convalescence. It is surprising how much the boost offered by a transfusion of blood will help some patients.

In ordering a blood transfusion the physician should not forget that intravenous administration always carries a certain risk. On the other hand if a blood transfusion is indicated it should be given. Each 500 cubic centimeters of blood administered raises the concentration of hemoglobin approximately ten per cent and increases the erythrocyte count about 500,000 cells per cubic millimeter. Hence no set amount should be agreed on for all patients. The patient should be given that amount of blood which fulfills the purpose of the transfusion. That amount is not necessarily administered in one transfusion but may be given in a series of transfusions.

THOMAS H SELDON

BLOOD PLASMA

WAR experience has helped to define the usefulness and limitations of blood plasma. The great abundance of plasma available to the armed forces of the United States led to an extensive clinical trial unhampered by supply or economic considerations. The purity and excellence of the plasma and the disposable sterile pyrogen free dispensing set provided allowed administration of large quantities of plasma

to individual patients without fear of reaction. An occasional allergic reaction manifested by urticaria was about the only reaction which could be definitely ascribed to plasma. However physiological disturbances some of extreme gravity, did result from its improper use.

Of greatest importance is the knowledge gained with the use of plasma and whole blood in wound shock. Early experience demonstrated that those who were resuscitated from shock by the administration of plasma presented a severe secondary anemia in convalescence. Further, those in extreme shock could be resuscitated only with the administration of whole blood. Later laboratory investigations of blood volumes and hematocrit readings demonstrated definitely that lowered blood volume was the important factor in wound shock and that the lowered blood volume was due to loss of whole blood rather than plasma, with certain few exceptions. Plasma therefore is not the ideal agent in most cases of wound shock and when so used is frequently a poor substitute for whole blood. When used to restore blood volume it dilutes the remaining red cells. If blood loss has been large the resulting diluted blood may be so deficient in red cells as to be ineffective as an oxygen carrier in the seriously wounded individual who must have surgical care.

Appreciation of these facts led to the adoption of certain principles of management. The wounded admitted to hospitals in severe shock with no brachial blood pressure were immediately and rapidly given low titer group O blood¹ without waiting for grouping and cross matching of the first liter. Those in less severe shock were administered plasma only while grouping and cross matching were rapidly completed. Forward of hospital units where whole blood was not available plasma was

¹Group O blood with anti-A and anti-B agglutins in titer less than 1:64.

given to those in shock in a quantity only sufficient to render them transportable to the nearest hospital unit where whole blood and facilities for surgery were available.

The necessity for whole blood in restoring blood volume was most apparent in those casualties with severe or multiple wounds. If large quantities of plasma were used in resuscitating such individuals they did not tolerate prolonged anesthesia and surgery necessary to the care of their wounds. When whole blood was used in adequate quantities surgical procedures were well tolerated and frequently extended over a period of many hours. The amount of blood required before and during surgery frequently totalled 3500 to 5000 cubic centimeters and occasionally more was required. In those with minor degrees of shock accompanying wounds which were not extensive and severe resuscitation and surgical care were occasionally accomplished with or following plasma therapy and no blood. However the margin of safety is certainly greater if every individual in shock from war wounds, or similar injuries receives some whole blood before or during surgery.

While whole blood loss alone accounts for the reduced blood volume in wound shock in the vast majority of cases there are a few exceptions. In certain abdominal and thoraco-abdominal wounds where there is gross contamination or sepsis in the peritoneum or pleura, plasma loss from exudation does occur. These cases most often have whole blood loss from their wounds in addition to the plasma loss. In some cases the whole blood loss is minimal and the plasma loss from exudation is maximal. When the latter situation was discovered at surgery plasma alone was used in the continued effort to combat shock.

Plasma loss and hemoconcentration were also found to occur in fulminating cases of clostridial myositis or gas gangrene of the wet

type. This loss of plasma through the wound or into the involved muscles was best combated with the infusion of large quantities of plasma. These same cases also tended to present a severe anemia and whole blood was necessary as well as plasma.

In cases of burn shock, unless complicated by wounds, the reduced blood volume is due almost entirely to plasma loss. The most common error in the management of burn shock is the failure to administer plasma rapidly enough and in sufficient amount. Best results were secured when the plasma was given as an emergency measure administering it into two veins or with positive pressure, if necessary to rapidly restore the hematocrit reading to normal. Once a normal reading was obtained the administration was continued at a sufficient rate to maintain this normal reading. As much as 4000 to 6000 cubic centimeters of plasma were used in the first twenty-four to thirty-six hours in extensive burns. With adequate and energetic therapy burn shock could almost always be controlled. Whole blood was not found necessary in the first thirty-six hours in the management of uncomplicated burns. Secondary anemia developed rapidly thereafter however and whole blood then replaced plasma in burn management.

Hemoconcentration and the need for the infusion of large quantities of plasma were found also in crush injuries. The tremendous swelling which developed in the limbs of these unfortunate victims after they were moved from beneath stones and masonry often led to very high hematocrit readings. Their management was often complicated by the development of pigment nephropathy and anuria.

In wartime plasma was used extensively to correct and prevent hypoproteinemia. Amino acid solutions for intravenous use were never generally available and were not available at

all until late in the war. Patients with severe wounds invariably showed some degree of hypoproteinemia and in those with abdominal wounds in whom nasogastric suction was continued over a period of days, hypoproteinemia became severe unless plasma was given in proper amounts. It became routine practice to give these patients 500 to 1000 cubic centimeters of plasma daily beside the whole blood needed. Plasma protein determinations by the copper sulfate specific gravity method indicated that 500 to 750 cubic centimeters of plasma daily was sufficient to maintain a satisfactory level in most patients of this sort.

Plasma has a definite and important place in peacetime surgery. It should be available everywhere for emergency management of the shock of severe burns. It should likewise be available for the management of traumatic shock to sustain life until whole blood is available. Its limitations in the management of shock should be well known so that it is not given in large quantities when whole blood is needed. A program to provide properly prepared and packaged plasma at low cost for emergency use throughout the nation would appear to be desirable.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE recent book by I. S. Smillie¹ encompasses the intricate and difficult task of describing the injuries to the knee joint in a comprehensive monograph. The author presents the subject in a manner which is outstanding in more than one sense. As would be expected a large portion of the book is given over to the discussion of what is commonly called internal derangement of the knee—that is the lesions of the menisci and the intrinsic ligaments. Another deals with the injuries of the collaterals, a third with those of the extensor apparatus, a fourth with the joint fractures, bones and injuries to the surrounding soft tissues. The most gratifying feature is that the author so happily combines precision and clearness in the clinical presentation with conciseness and lucidity in developing for his readers the basic background of mechanogenesis and pathology.

The discussion of the semilunar cartilage injuries is an example. The diagnosis is based on observational points inclusive enough to protect the clinician against disappointment.

With all the weight that is laid upon the comprehensive description of all diagnostic features and their evaluation, one finds there is no tendency to introduce unusual or occasional observations nor to confuse the issue by elevating these to the dignity of diagnostic landmarks, as is so often done in monographs of this kind. Consequently one will find much which is hardly worth mentioning has been left unsaid.

In each particular section the pertinent facts of mechanogenesis and pathology are stated simply and clearly and their clinical implications are stipulated with a great deal of plausibility. For instance the manner of occurrence, the nature and the signs of the different types of meniscal tears. The same can be said of the chapters that deal with the injuries of the collaterals and with the loose intra-articular bodies. There is another redeeming feature about this book, namely that there is throughout a wholesome tendency of conservatism. While the operative side is discussed comprehensively and one cannot say that any of the current operative methods are omitted, yet it is not given undue prominence. An instance is the emphasis laid upon the development of the quadriceps extensor apparatus as a conservative therapeutic measure.

In fact the introductory chapter is devoted to the importance of the quadriceps. This is followed in logical sequence by one on secondary traumatic

synovitis and hemarthrosis. The surgical anatomy and the specific pathology are dealt with separately along with the individual topics and one will find this presentation clear, concise, and thoroughly adequate. One chapter devoted to fractures of the tibia and fibula which involve the knee joint is quite attractive, as is the one dealing with the wounds of the knee. Nevertheless, the outstanding chapters, we believe are those dealing with the internal derangement, those on the collaterals and the free joint bodies, the injuries of the extensor apparatus and, above all, those sections which present prevention and treatment of posttraumatic functional deficiencies by conservative measures.

The wide experience of the author is amply demonstrated by imposing statistics. There is an abundance of roentgenograms covering all illustrative cases, each one bringing out a specific clinical situation they are numerous and yet do not tire the reader by duplication. Illustrations are excellent, both those in color and those which appear as diagrammatic drawings. In its particular field the book certainly can claim to be a classic.

ARTHUR STEINBERG.

IN a profusely illustrated volume of 350 pages the author of *Demonstration of Physical Signs in Clinical Surgery*² describes the more common physical signs in surgical diagnosis. There are 573 illustrations, most of which are photographs, many in color. Although many of the photographs are old they are quite satisfactory. The colored photographs are excellent and admirably illustrate the lesion in question. The text is brief and used chiefly to describe the illustrations and the various signs and tests they illustrate. Credit is given by means of footnotes to those men originally describing a sign or test. The book will be found useful by the student meeting these findings for the first time.

THOMAS C. DOUGLASS.

THE book *The Essentials of Obstetrics and Gynecology*³ by Scott and Van Wyck is based on the lectures in obstetrics and gynecology given at the University of Toronto. It is divided into two parts, the first covering obstetrics and the second gynecology.

¹DEMONSTRATION OF PHYSICAL SIGNS IN CLINICAL SURGERY. By HENRIETTA BAKER F.R.C.S. (Eng.), F.R.C.S. (Ed.), F.R.C.S. (Ireland). The Williams & Wilkins Co. 1946.

²THE ESSENTIALS OF OBSTETRICS AND GYNECOLOGY. By WILLIAM ALBERT SCOTT, B.A., M.B., F.R.C.S. (Oxon.), F.R.C.O. (Eng.), and H. BROOKFIELD VAN WYCK, B.A., M.B., F.R.C.S. (Oxon.), F.R.C.O. (Eng.). Philadelphia: Lea & Febiger, 1946.

INJURIES OF THE KNEE JOINT. By I. S. SMILLIE, O.B.E., M.B., F.R.C.S. (Ed.), F.R.F.P.S. Baltimore, Md. The Williams & Wilkins Co. 1946.

Part one obstetrics is divided into three sections. Section one covers normal obstetrics. The initial chapter is concerned with a well written and brief discussion of the embryology of the genital system. It also includes a short description of pelvic anatomy which is adequate for the medical student to orient himself. Physiology is divided into a discussion of the changes in the various periods of a woman's life, and is briefly covered in a style that should be easily understood by the student. The physiology of conception is carried along in a sequence that follows logically and reads easily. The discussion of the puerperium is excellent. It is presented concisely with fundamentals and commonly met problems outlined in a practical manner.

Section two deals with abnormal obstetrics. Toxemia, abortion, premature labor and bleeding are outlined. The diseases complicating pregnancy are briefly discussed. Syphilis could probably have been given more discussion, especially an outline of therapy. Diabetes also deserves more mention, even in an outline type of text. The Rh factor is mentioned and discussed in relation to erythroblastosis fetalis and even though our knowledge of the relationship and management is meager, a more complete discussion might have been warranted.

Section three deals with operative obstetrics. The views expressed are conservative and sound. One illustration shows three types of obstetrical forceps, all of which are designed for the more difficult types of operations. One wonders why the more commonly used instruments are not shown. Two illustrations of instruments used in destructive operations are also shown, but in the short résumé of this operation no mention is made of their specific application.

Part two covers gynecology and is presented in a well planned outline manner. The various gynecological disorders are discussed according to location, starting with the vulva and progressing upward. The discussion of Leucoplakia fails to mention the more than casual relationship to carcinoma, however, later under the latter heading this relationship is brought out. Carcinoma of the cervix and corpus is briefly but well covered. The use of illustrations in describing these conditions would have been helpful. The authors favor radiation therapy for cervical malignancy and radiation followed by surgery for that in the body of the uterus.

Ovarian tumors are classified in a simple outline form. The treatment of pelvic infections has been given conservative handling. Sulfadiazine is stressed in the treatment of gonorrhea, and penicillin is only mentioned as a hospital treatment for speedy cure. More detail about its use might have been given.

The chapter on endometriosis covers the cardinal points in the disease. Sterility and acquired dys-

menorrhea and the more than casual relationship between fibroids, retrodisplacement, and endometriosis might have been stressed more.

A good outline of the causes of vaginal bleeding is presented and diagnostic points in differentiation have been emphasized.

Gynecologic operative procedures are covered in twenty-one pages. Stress is placed on good surgical technique, careful handling of tissues and hemostasis. A short outline of sensible postoperative care is given. The details of various special operations have been limited throughout, except for a series of illustrations showing the steps in performing a Manchester operation for prolapse. The authors apparently favor this procedure.

This short volume outlining both obstetrics and gynecology should be helpful to students. The authors have adhered to the essentials with the elimination of theory and controversial discussion.

GEORGE B. BRADBURN

THE book entitled *Uterine Contractility in Pregnancy* is based on some 3,200 individual records of the contractions of 1,200 pregnant women, taken during both pregnancy and labor by means of the Lorand tycograph. The observations have a practical value because they demonstrate the close relationship which exists between the quality of the contractions of pregnancy and that of the same woman during her labor. It was found that each individual possesses her own contraction pattern which persists with relatively little modification throughout all of gestation.

The studies also indicate how a knowledge of the quality of the contractions which appear early in labor can assist the obstetrician in predicting the future quality of the contractions as labor advances and in distinguishing between inertia and disproportion as causes of prolonged labor. Furthermore, the studies made with the utilization of oxytocic drugs emphasize the necessity of using very small and accurately measured doses of such drugs in the treatment of uterine inertia.

The book is the result of diligent studies made over a period of several years. In the list of references are nineteen publications of Murphy on this subject. The text is well written and easy to read, the type is clear, the charts and tables are instructive, and the paper is of good quality. Anyone interested in obstetrics will find a good deal of information about uterine contractions in both normal and abnormal labor which can be applied in daily practice.

J. P. GREENHILL.

UTERINE CONTRACTILITY IN PREGNANCY. By Douglas P. Murphy, M.D. F.A.C.S. Philadelphia, London, Montreal: J.B. Lippincott Co. 947

CORRESPONDENCE

A NEW TECHNIQUE FOR PULMONARY SEGMENTAL RESECTION ITS APPLICATION IN THE TREATMENT OF BRONCHIECTASIS—
A Correction

To the Editor In the article entitled A New Technique for Pulmonary Segmental Resection Its

Application in the Treatment of Bronchiectasis which appears on pp 257-268 of the March, 1947 issue of SURGERY GYNECOLOGY AND OBSTETRICS an error has been made in the arrangement of Figures 8, 9, 10 and 11. Figures 10 and 11 should appear on p. 262 as Figures 8 and 9, and Figures 8 and 9 should appear on p. 263 as Figures 10 and 11.

[illegible]

PRELIMINARY PROGRAM FOR 1947 CLINICAL CONGRESS
THE WILDORF ASTORIA NEW YORK
SEPTEMBER 8 TO 12, 1947

PASS a page or two of the first issue of the *Journal of Clinical Gerontology*. The American Geriatrics Society has been instrumental in the development of this journal, a journal which will provide the most complete and comprehensive information for the gerontologist in any specialty field. The journal is published twice a year, and the first issue will be published in the fall of 1976. The journal is published by the American Geriatrics Society, 1100 North Dearborn Avenue, Chicago, Illinois 60610. The price of each issue will be \$10.00. The journal is published by the American Geriatrics Society, 1100 North Dearborn Avenue, Chicago, Illinois 60610. The price of each issue will be \$10.00. The journal is published by the American Geriatrics Society, 1100 North Dearborn Avenue, Chicago, Illinois 60610. The price of each issue will be \$10.00.

And one of the scope of the clinical program may be obtained from consulting the August 1941 issue of Surgery, Gynecology and Obstetrics, pages 2551 to 2558 in which was published the preliminary program prepared last year before the Clinical Congress was transferred from New York to Cleveland.

THE FARM IS USITAI

The usual varied and comprehensive program for meeting at the headquarters hotel will start at 10. The first central lecture will be held on the evening of September 5 in the Grand Ball room with the inaugural ceremony for the incoming officers and the Presidential Address by Dr. Lynn Mel'ard and the delivery of the second Martin Memorial Lecture. The Convention includes the presentation of certificates for life membership, the presentation of a ship and the delivery of the Life-Ship Address, which will be held on the evening of September 12. Other official meetings include the Annual Meeting of Fellows on September 14, the Assembly of Initiates on September 15, meetings of the Board of Regents and of the Governors, and meetings of various committees.

Evening sessions will be held on Tuesday, Wednesday and Thursday devoted to subjects in the field of general surgery and also in ophthalmology and otolaryngology which will be featured in separate meetings.

Afternoon sessions will consist of panel discussions led by recognized authorities in their respective field who will be aided by well qualified collaborators. Preliminary plans include the holding on one afternoon of a symposium on fractures and other traumas and on another afternoon of a symposium on cancer. A number

of panels on the surgical specialties are planned for the final afternoon.

Morning meetings will include separate panel discussions at 11:00 o'clock on Tuesday Wednesday and Thursday for ophthalmologists and otolaryngologists.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems will be conducted on Tuesday Wednesday, Thursday and Friday mornings. Included will be brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties. No prepared discussions of the reports are planned but questions and comments will be invited. Dr Owen H. Wangenstein of Minneapolis, chairman of the committee which is planning the program, is working toward representation of as many as possible of the various university departments of surgery in this presentation of clinical and experimental research work.

The enlistment of the interest of young men who are doing original work, through the Forum, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty-sixth Hospital Standardization Conference. Dr Irvin Abell of Louisville, President of the College, will preside. The hospital conferences will continue on Monday afternoon, with sessions following on Tuesday Wednesday and Thursday mornings, afternoons, and evenings.

Hospital administrators, members of governing boards, heads of the various hospital departments and their personnel nursing groups, and many other persons directly or indirectly concerned about hospital progress will be interested in the discussion of current hospital problems. National organizations representing various groups of hospital personnel will co-operate and participate in the meetings, which will include formal sessions, panel discussions, round table conferences, and open forums.

ADVANCE REGISTRATION

The hospitals and medical schools of New York afford accommodations for a large number of visiting surgeons. However in order to insure against overcrowding, attendance at the Congress will be limited to the number that can be comfortably accommodated at the meetings and also by ac-

commodations in the hotels. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

The members of the Board of Regents regret that conditions beyond their control will not permit unpaid registration at the 1947 Clinical Congress. They voted to restore the registration fee of \$5.00 for Fellows and for endorsed Junior Candidates. Non-Fellows attending as invited guests of the College will pay a fee of \$10.00. No fee will be required of initiates of the class of 1947.

To each surgeon who registers in advance a formal receipt will be issued. This is to be exchanged for a general admission card upon his registration at headquarters during the Congress. This card is not transferable and must be presented in order to obtain clinic tickets and admission to scientific sessions.

MEDICAL MOTION PICTURES

The latest available films showing surgical procedures and related subjects will be shown in the medical motion picture exhibits which will be held daily. These are a much appreciated feature of the Clinical Congress.

Both sound and silent, standard and color films will be shown, all of which have been approved by the Committee on Medical Motion Pictures.

TECHNICAL AND SCIENTIFIC EXHIBITION

The technical exhibit, together with the registration and clinic ticket bureaus, will be located in the Basilidon Room, Jade Room, and Astor Gallery all on the third floor of the hotel. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds, and pharmaceuticals, and publishers of medical books will be represented in the exhibition. The technical exhibits will demonstrate many of the newer features learned from our experience in the war.

HOTEL RESERVATIONS

Although the prospect is that the hotel situation in New York will be more favorable than it would have been last year nevertheless there is still a critical shortage of hotel rooms and early reservations are most desirable. In making these, communications should be addressed to the New York Convention Bureau through which all reservations for the Clinical Congress are to clear. No correspondence should be sent directly to the hotels. A letter has been sent to Fellows in which the procedure is outlined with this letter was enclosed a form to be used in making

reservations. First, second, third, fourth, and fifth choices of hotels may be designated. The following hotels are recommended by the Committee

	Midtown rates with Bath	
	Single	Double
Albion House, 143 East 39th Street	\$2 75	\$
Albion House for Women, 130 East 57th Street	3 00	
Ambassador, Park Avenue and 51st Street	6 00

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday

- 9:30 General Assembly for Surgeons and Hospital Representatives, Grand Ballroom
- 9:30-1000 Panel Discussion, Wedgwood Room
- 1000 Clinical Demonstrations and Clinical Group Conferences, selected local hospitals
- 1100 Hospital Conference, Sert Room
- 1200 Surgical Film Exhibition (General), Grand Ballroom
- 1:30-5:00 Panel Discussion, Wedgwood Room
- 8:15 Presidential Meeting, Grand Ballroom

Tuesday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-1:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear Nose and Throat), Jensen Suite
- 1000 Surgical Film Exhibition (General) Wedgwood Room
- 1100 Panel Discussions
 - Ophthalmology—Otorhinolaryngology
- 1:30-3:00 Panel Discussion, Grand Ballroom
- 3:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 4:00 Hospital Conference, Sert Room
- 5:00 Symposium on Fractures and Other Traumas
- 6:00 Surgical Film Exhibition (General) Wedgwood Room
- 7:30-12:00 Panel Discussion, Grand Ballroom
- 7:00 Surgical Film Exhibition (Eye, Ear Nose and Throat), Wedgwood Room
- 7:30 Hospital Conference—Trustees, Sert Room
- 8:00 Scientific Session, General Surgery Grand Ballroom
- 8:00 Scientific Session, Ophthalmology Jensen Suite
- 8:00 Scientific Session, Otorhinolaryngology Le Perquet Suite

Wednesday

- 8:00 Meeting of Cancer Committee, Carpenter Foyer and Dining Room
- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear Nose and Throat)
- 1000 Surgical Film Exhibition (General)

State and Provincial Committees

- 9:30 Executive Committees
- 9:15 Credentials Committees and Committees on Appointments } Wedgwood Room
- 1000 Judiciary Committees
- 1100 Panel Discussions
 - Ophthalmology
 - Otorhinolaryngology
- 1200 Meeting of Board of Governors, Jensen Suite
- 3:00-3:30 Panel Discussion, Grand Ballroom
- 4:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 5:00 Symposium on Cancer Wedgwood Room
- 6:00 Surgical Film Exhibition (General)
- 8:00 Hospital Conference, Sert Room

- 7:30-9:00 Panel Discussion, Grand Ballroom
- 6:00 Vandyck Reunion Dinner Le Perquet Suite
- 7:00 Surgical Film Exhibition (Eye, Ear Nose and Throat) Wedgwood Room
- 7:30 Hospital Conference, Sert Room
- 8:00 Scientific Session, General Surgery Grand Ballroom
- 8:00 Scientific Session (Eye, Ear Nose and Throat), Empire Room

Thursday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Hospital Conference, Sert Room
- 9:30 Surgical Film Exhibition (Eye, Ear Nose and Throat)
- 10:00 Surgical Film Exhibition (General) Wedgwood Room
- 1100 Panel Discussions
 - Ophthalmology
 - Otorhinolaryngology
- 3:00 Adjourned Meeting, Governors, Grand Ballroom
- 1:45 Annual Meeting, Fellows, Grand Ballroom
- 2:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 3:00 Hospital Conference, Sert Room
- 3:00 Panel Discussion—Graduate Training in Surgery Jensen Suite
- 3:30-5:00 Panel Discussion, Grand Ballroom
- 3:30 Surgical Film Exhibition (General), Wedgwood Room
- 3:30 National and Regional Fracture Committee, Le Perquet Suite
- 4:00 Committee on the Library Room 4-J
- 7:00 Surgical Film Exhibition (Eye, Ear Nose and Throat), Wedgwood Room
- 8:00 Scientific Session, General Surgery, Grand Ballroom
- 8:00 Scientific Session, Ophthalmology Wedgwood Room
- 8:00 Scientific Session, Otorhinolaryngology Sert Room

Friday

- 8:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 9:00-12:30 Forum on Fundamental Surgical Problems, Grand Ballroom
- 9:30 Surgical Film Exhibition (Eye, Ear Nose and Throat)
- 10:00 Surgical Film Exhibition (General) Wedgwood Room
- 1100 Assembly of Initiates, Grand Ballroom
- 1200 Panel Discussion, General Surgery
- 1:00 Clinics, Demonstrations and Clinical Group Conferences, selected local hospitals
- 2:00-4:00 Panel Discussions
 - Obstetrics, Sert Room
 - Plastic Surgery 4 U Blue Room
 - Neurological Surgery Assembly Room M N
 - Thoracic Surgery Jensen Suite
 - Urology Le Perquet Suite
 - Orthopedic Surgery Carpenter Foyer and Dining Room
- 3:00 Surgical Film Exhibition (General) Wedgwood Room
- 3:30 Panel Discussion, General Surgery
- 8:15 Convocation, Grand Ballroom

Address of retiring president, Ideals in surgery 513
Board of Regents of considers delays in appointments to hospital staffs, 1018
Clinical Congress, in Cleveland, General Review 1946 888 Cleveland committee on arrangements—hospitals and representatives, 889, Exhibitors In 1946 technical exhibition 890 Clinical Congress, 1947, Preliminary program for New York, September 8 to 12 1947 1014, 1131
Fracture union, Modern methods in treatment of fractures, 563
Franklin H. Martin memorial lecture, American surgeon, A.U.S. 539
Graduate training in surgery 886
Surgical forum, 531
- Amputations**, anatomic disarticulation of hip 346 Principles involved in surgical therapy in encapsulated fibrosarcomas of soft tissues, 703 Major 759 Radical, of extremities in treatment of cancer 1105
- Anatomist**, Interdependence of artist and 376
- Anatomy**, Applied, In eye surgery 777
- Anemia**, Value of red cell transfusions, ed. 997 in burns, ed. 999, Importance of blood in preoperative and post operative treatment, ed. 1124
- Anesthesia**, Physiologic effects of curare and its use as adjunct to, 491 Circulatory and respiratory distress from extreme positions on operating table, 1051
- Aneurysm**, arteriovenous, Choice of operation for treatment of arteriovenous fistulas, 903
- Antibiotics**, Excretion and concentration of penicillin and streptomycin in abnormal human biliary tract. I. Gall bladder 16 Correlation of use of and chemotherapeutic agents with general principles of surgery 789 Indications for surgery in light of use of 850 Intranasal surgery 850
- Anticoagulants**, in venous thrombosis and prevention of pulmonary embolism 665 therapy in thrombosis, 677
- Antrum**, External sinus surgery 853 Preservation of jaw function following surgery and trauma, 870
- Auria**, burn, crush, hemorrhage, Studies on, effect of infusion fluids and diuretics on, resulting from severe burns, 283
- Anal**, Histopathology of anal ducts, 333 Results of treatment of epidermoid carcinomas of and rectum, 967
- Aorta**, Thoracoabdominal approach to upper abdomen, 331 abdominal, Complete occlusion of with report of 2 patients diagnosed by means of aortography 619 Experimental aortic valvulotomy preliminary report, 625
- Aortography** Complete occlusion of abdominal aorta, report of 2 patients diagnosed by 619
- Approach**, Axillary to Schede thoracoplasty 55
- Argyrol kaolin lactose powder** Treatment of Trichomonas vaginalis vaginitis, 891
- Arm** New operative treatment for elephantiasis, 642 Major amputations, 759 Radical amputations of extremities in treatment of cancer 1105
- Arrhenoblastoma** Masculinizing tumors of ovary clinicopathologic survey with discussion of histogenesis and report of 3 cases, 213
- Artery** Blood supply of kidney suprarenal gland, and associated structures, 313 Coagulation thrombi in segments of artery and vein in dogs and genesis of thromboembolism 451 renal, Complete occlusion of abdominal aorta report of 2 patients diagnosed by aortography 619 Arteriovenous fistula, experimental study of influence of sympathetic nervous system on development of collateral circulation 629 surgery choice of operations for treatment of arteriovenous fistulas, 903
- Artist** Interdependence of and anatomist, 376
- Ascites**, Certain pelvic tumors associated with and hydrothorax, 181
- Ascorbic acid**, Experimental study in wound healing in vitamin C depleted human subjects, 1
- Aspiration biopsy** of lymph nodes, critical review of results of 300 aspirations, 1071
- Atresia**, Congenital, of esophagus with tracheoesophageal fistula, ed. 504
- BASKET** Implant, New type of for use after enucleation 703
- Bile**, hepatic, Excretion and concentration of penicillin and streptomycin in abnormal human biliary tract. II Hepatic bile 140
- Bile ducts**, Resection of common hepatic duct for papillary adenocarcinoma, 487 Experimental implantation of common into intestine, 607
- Biliary drainage**, Pathological physiology of use of new type of T-tube and criteria for its removal 174
- Biliary system**, Simplified repair of common duct, use of umbrella catheter to produce internal biliary fistula 321
- Biliary tract**, Excretion and concentration of penicillin and streptomycin in abnormal human. I. Gall bladder 16 Excretion and concentration of penicillin and streptomycin in abnormal human biliary tract II Hepatic bile 140 Pancreatic reflux deliberately produced 710
- Bladder** Total cystectomy by combined perineoabdominal method, 90
- Blood**, Coagulation thrombi in segments of artery and vein in dogs and genesis of thromboembolism 451 Use of and, substitutes, 601 Anticoagulant therapy in thrombosis, 677 Gelatin solution in treatment of shock from graded hemorrhage 925 Value of red cell transfusions, ed. 997 Anemia in burns, ed. 999 Importance of in preoperative and postoperative treatment, ed. 1124
- Blood loss**, Estimation of acute, by tilt test, 1045
- Blood plasma**, ed. 1125
- Blood pressure**, Extensive combined thoracolumbar sympathectomy in hypertension 1117
- Blood stream** Clinical uses of streptomycin in medicine and surgery 579
- Blood substitutes**, Use of blood and, 601
- Blood transfusions**, Importance of blood in preoperative and postoperative treatment, ed. 1124

- Blood vessels, Blood supply of kidney suprarenal gland and associated structures, 335 Interruption of deep veins of lower extremities in prevention and treatment of thrombosis and embolism, 59 Ligation of inferior vena cava in thrombosis of deep veins of lower extremities, 605 Arteriovenous fistula, experimental study of influence of sympathetic nervous system on development of collateral circulation, 640 Anomalies of pulmonary veins, their surgical significance, 653 Sympathetic interruption in cases of trauma and in posttraumatic states, 750 Extensive hemangioma, 897, anastomosis, Comparison of suture and nonsuture methods for anastomosis of veins, 939
- Blood volume, Estimation of acute blood loss by tilt test, 1045 Blood plasma, ed. 5
- Body fluid equilibrium, Fluid and electrolyte balance, 566
- Bones, long, Medullary nailing of fractures of 85 Clinical experiences with use of penicillin treatment of infections involving, and joints, 269 Massive iliac grafts in treatment of ununited fractures and large defects of long, combined, graft metallic plate technique, analysis of 9 operations in 85 patients, 435
- Bone chips, Resection of clavicle, with particular reference to use of in periosteal bed, 245
- Bone grafts, iliac Massive, in treatment of ununited fractures and large defects of long bones, combined, metallic plate technique, analysis of 9 operations in 85 patients, 435 Cancellous, to jaw 653 Advances in, surgery attributed to World War II 763 Osteomyelitis following compound fractures, 775
- Book shelf, Shenandoah tragedy, 5 Interdependence of artist and anatomist, 376 Did cholera defeat Custer 1003 Psychiatrist looks at Custer 012
- Breast, hypertrophy Reconstructive surgery of chest wall, 465 Use of male sex hormone in women with, cancer 719 Circumscribed chronic suppurative mastitis simulating cancer 935
- Breast carcinoma, Reconstructive surgery of chest wall, 465
- Bronchiectasis, New technique for pulmonary segmental resection, its application in treatment of 257 cor 30
- Bronchus, New technique for pulmonary segmental resection, application in bronchiectasis, 37 cor 130
- Burns, Studies on anuria, effect of infusion fluids and diuretics on anuria resulting from severe, 285 Closure of surface defects with free skin grafts and with pedicle flaps, 862 Anemia in, ed. 999, Blood plasma, ed. 115
- C**ANCER, Growth of human trophoblast in eye of rabbit its relationship to origin of, preliminary report, 301 Use of male sex hormone in women with breast, 79 Resection of intra-abdominal, that has invaded anterior abdominal wall, 73 Observations on genetic nature of gastric, in mice, 737 circumscribed chronic suppurative mastitis simulating, 935 Anal colectomy with preservation of sphincter in patients requiring total colectomy for benign lesions, 095 Radical amputations of extremities in treatment of 05
- Carcinoma, Evolution of adenomas of large intestine and their relation to, 36 Gastric, comparative review of origin, diagnosis, and end-results in 585 patients, 45 of colon, statistical analysis, 669 epidermoid, Results of treatment of of anus and rectum, 667, gastric, Histo-pathology of sebaceous epidermal layer 953
- Carpal scaphoid, Fracture of 769
- Cartilage, implants, Surgical substitutions for losses of external ear simplified local flap method of reconstruction, 0 cor 1, Infections of, and sternum, 018
- Catgut, Rate of gain in strength in sutured abdominal wall wounds, 685
- Cecum, Cecostomy and Miller Abbott tube, report on their combined use in preparation of obstructed large bowel for surgery 1083
- Cells, Effect of radiation on vaginal cells in cervical carcinoma, I. Description of cellular changes, 55; II. Prognostic significance, 166 Cancer of cervix, ed. 249
- Chemotherapy Some observations on wound healing, clinical study with note on topical chemotherapy and secondary closure, 203 Penicillin—its use in surgery and influence on earlier types of, 540 Correlation of use of antitoxic and chemotherapeutic agents with general principles of surgery 729, Physiological aspects of surgical infections, 733 Indications for surgery in light of use of antibiotics, 850
- Chest, Reconstructive surgery of, wall, 465 Infections of costal cartilages and sternum, 38
- Chest wall, Reconstructive surgery of 465
- Chin, Cancellous bone grafts to jaw 553
- Cholera, Did, defeat Custer 1003
- Choriocarcinoma, Growth of human trophoblast in eye of rabbit its relationship to origin of cancer, preliminary report, 301
- Circulation, collateral, Arteriovenous fistula, experimental study of influence of sympathetic nervous system on development of, 640 Effect of mechanical artificial respiration upon maintenance of 1059
- Circulatory distress, and respiratory from extreme positions on operating table, 1051
- Clavicle, Resection of, with particular reference to use of bone chips in periosteal bed, 245
- Cleft palate, Surgical correction of nasal deformities, 66
- Studies in anatomy and repair of 878
- Closure, secondary Some observations on wound healing, clinical study with note on topical chemotherapy and, 203
- Colectomy Anal, with preservation of sphincter a proposed operation in patients requiring total colectomy for benign lesions, 095
- Colon, Complete fecal diversion achieved by a simple loop colectomy 409 Carcinoma of, statistical analysis, 669
- Colostomy Complete fecal diversion achieved by simple loop, 409
- Common duct, Simplified repair of, use of umbrella catheter to produce internal biliary fistula, 31
- Cotton, Complications following use of, as suture material, 3
- Council of National Defense World War I, American surgeon, A.U.S., 559
- Curare, Physiologic effects of and its use as adjunct to anesthesia, 49
- Custer George Armstrong, Did cholera defeat, 003 Psychiatrist looks at, 2
- D**EAFNESS, Fenestration operation, evaluation of its present status, 893, conductive, Use of radium in treatment of 830 Consideration of hearing impairment in treatment of chronic suppurative otitis media, 845
- Diagnosis, Aspiration biopsy of lymph nodes, critical review of results of 300 aspirations, 071
- Dicoumarol, Ligation of inferior vena cava in thromboembolism, report of 36 cases, 385 Anticoagulants in venous thrombosis and prevention of pulmonary embolism, 665 Anticoagulant therapy in thrombosis, 677
- Diet, Nutritional preparation for substandard risk patients, 6
- Digestion, of living tissue, by hyperacid stomach, experimental study 959
- Doctors, Problems of nurses and, ed. 1

Drainage, high vacuum suction, Treatment of chronic nontuberculous pulmonary abscesses by 652
 Ducts, anal, Histopathology of 333 hepatic, Resection of common, for papillary adenocarcinoma, 427
 Duodenum, Diverticula of stomach and, treatment by in vagination and suture, 292

EAR, Surgical substitutions for losses of external, simplified local flap method of reconstruction, 192 Fenestration operation, evaluation of its present status, 828
 Electrodiagnosis, Strength-interval curves and repetitive stimuli in, 1077

Electrolyte balance Fluid and, 586
 Elephantiasis, New operative treatment for 642
 Embolism Interruption of deep veins of lower extremities in prevention and treatment of thrombosis and, 519, pulmonary Anticoagulants in venous thrombosis and prevention of, 665
 Epithelium lined flap, Reconstruction of upper lip, 804
 Esophagus, Reconstruction of by skin-lined tube, 197
 Thoracoabdominal approach to upper abdomen 331
 Progress in surgical treatment of carcinoma of, ed. 373
 Congenital atresia of with tracheoesophageal fistula, ed. 504

Esophage, postoperative, Ligation of inferior vena cava in thrombosis of deep veins of lower extremities, 605
 Enophthalmos, Unilateral, early sign in thyrotoxicosis, 326
 Extremities, Radical amputations of in treatment of cancer 1105

Eye, Growth of human trophoblast in of rabbit Its relationship to origin of cancer preliminary report, 301
 Applied anatomy in, surgery 777 Management of strabismus in children, 787 New type of basket implant for use after enucleation, 792 Reconstruction of orbital floor defects, 799 Management of nonmagnetic intraocular foreign bodies, 809 Visual field defects due to head injuries, 823
 Eyelid, Reconstruction of upper lid, 804

FACE, Neutralization of color in capillary hemangiomas of, by intradermal injection (tattooing) of permanent pigments, 866

Facets, Surgical fusion of vertebral articular technique and instruments employed, 50
 Fecal diversion, Complete, achieved by simple loop colostomy 409

Federated Surgical Society of America, Surgeon and his trust, with special reference to safe conduct of patient through operation, 567

Feet, Fractures of os calcis, ed. 374 New operative treatment for elephantiasis, 642 Radical amputations of extremities in treatment of cancer 1105

Femur Supracondylar shortening of for leg length inequality 1087

Fenestration operation, evaluation of its present status, 828
 Fibrin foam, Plasma fractions—thrombin, and "fraction No. 1"—in general surgery 361

Fibrosarcoma, Principles involved in surgical therapy in encapsulated, of soft tissues, 703
 Fingers, Major amputations, 759

Fistula, Arteriovenous, experimental study of influence of sympathetic nervous system on development of collateral circulation, 629, arteriovenous, Choice of operation for treatment of, 903

Fluid balance, and electrolyte, 586
 Fluorocopy, Gastric carcinoma, comparative review of origin, diagnosis and end results in 583 patients, 481

Foreign body Management of nonmagnetic intraocular foreign bodies, 809

Fraction No. 1, in general surgery 361

Fractures, Medullary nailing of of long bones, 85 Massive iliac bone grafts in treatment of ununited, and large defect of long bones, combined bone graft-metallic plate technique, analysis of 91 operations in 85 patients, 435 Modern methods in treatment of 562
 Transportation of soldiers with, 750 Advances in bone graft surgery attributed to World War II, 765 of carpal scaphoid, 760 compound Management of, in their early phases, 772 compound, Osteomyelitis following, 775 jaw Management of 973
 Fungus soluble, Clinical observations on, dressing in treatment of surface infections, 366

GALLBLADDER, Observations on use of, in surgical scrub 355
 Gall bladder Excretion and concentration of penicillin and streptomycin in abnormal human biliary tract. I. Gall bladder, 16 Resection of common hepatic duct for papillary adenocarcinoma, 427
 Ganglia, aorticorenal, celiac, 4th thoracic, and lumbar iliohypogastric, Extensive combined thoracolumbar sympathectomy in hypertension 5117

Ganglioneuroma, of sympathetic nervous system 101
 Gastrectomy, Total, for carcinoma of stomach, 21 Total, report of 80 cases, 402

Gastroscopy, Gastric carcinoma, comparative review of origin, diagnosis, and end results in 583 patients, 481

Gelatin solutions, Preliminary—study in prevention of hemorrhagic shock, 499 in treatment of shock from graded hemorrhage 925

Genetics, Observations on genetic nature of gastric cancer in mice, 727

Glaucoma, Applied anatomy in eye surgery, 777
 Glove powder Experiments with nonirritating 689

Glucose, Study of protein hydrolyzates, ossein gelatin and, in parenteral nutrition, 1065

Goster intrathoracic, Technique of thyroidectomy 259

Graduate training Ideals in surgery, 513

Graft, split, thickness, graft—useful adjunct in tube pedicle preparation, 97

Gunshot wounds, Closure of surface defects with free skin grafts and with pedicle flaps, 862

HARELIP, Surgical correction of nasal deformities, 65
 Head injuries, Visual field defects due to, 823

Hearing Use of radium in treatment of conductive deafness, 839

Hearing aids, Fenestration operation, evaluation of its present status, 828

Hearing impairment, Consideration of in treatment of chronic suppurative otitis media, 845

Heart disease, Experimental aortic valvulotomy preliminary report 625

Hemangiomas, Neutralization of color in capillary of face by intradermal injection (tattooing) of permanent pigments, 866 capillary cavernous, Extensive, report of cases, 897

Hemorrhage, Use of blood and blood substitutes, 601 graded Gelatin solution in treatment of shock from, 925

Hemorrhoidectomy, eliminating use of clamp 62

Hemostatic agents, Plasma fractions—"fibrin foam" thrombin and "fraction No. 1"—in general surgery 361

Heparin, Ligation of inferior vena cava in thromboembolism, report of 36 cases 385 Anticoagulants in venous thrombosis and prevention of pulmonary embolism, 665 Anticoagulant therapy in thrombosis, 677 Effect of mechanical artificial respiration upon maintenance of circulation, 1059

Hepatitis, chloroform Protective action of sulfanilamide on experimental 477

Hernia, Effect of early postoperative rising on recurrence rate of 76

Hip, Anatomic disarticulation of 346

Histamine injection, Digestion of living tissue by hyperacid stomach, experimental study 959

Hormone, male sex, Use of in women with breast cancer 719

Hydrothorax, Certain pelvic tumors associated with ascites and, 18

Hypertension, Extensive combined thoracolumbar sympathectomy in, 117

Hysterectomy, Carcinoma of corpus teri, end results of treatment in 33 cases from 1926-1940, 29

ILIAC bone grafts, Reconstruction of orbital bone defects, 799

Ilium, Origin and development of erect posture, 943

Inchons, Brock, Garlock, Humphreys, Loucks and Wu, and Ohmura, Combined thoracoabdominal approach with particular reference to its employment in spleenectomy 19

Infants, Congenital atresia of esophagus with tracheoesophageal fistula, ed 504

Infections, Clinical observations on furacin soluble dressing in treatment of surface 306 Physiological aspects of surgical, 733 wound, Action of urea and some of its derivatives on bacteria. IV Effect of mixture of urethane and sulfanilamide on bacterial flora of infected wounds in man 93

Instruments and apparatus—tenoscopy Experimental study in wound healing in vitamin C depleted human subjects, Meyerding hantematomy Surgical fusion of vertebral articular facets, technique and instruments employed, 50, T-4 to T-12 Foley bag, Pathological physiology of biliary drainage, use of New type of and criteria for its removal, 74 umbrella catheter Simplified repair of common duct, use of to produce internal biliary fistula, 3 metal splint, C necrotic bone grafts to jaw 553 used in fractures, Modern methods of treatment of fractures, 562 Wangersten, eighth machine Surgeon and his trust, 11 special reference to self conduct of patient through operation, 567, drip feeding, Nutritional preparation for substandard risk patients, 61 valvulotomy, Experimental aortic valvulotomy preliminary report, 65 tenoscopy Rate of gas strength in sutured abdominal wall wounds, 685 Murray Jones arm splint, Tobruk splint, Transportation of soldiers with fractures, 750 McNaughton slit-lamp, Applied anatomy eye surgery 777 basket implant plastic prostheses, New type of basket implant for use after excision, 79 Thorpe self-closing forceps, Management of nonmagnetic intracocular foreign bodies, 809 electromagnetic device for tattooing Neutralization of color in capillary hemangiomas of face by intradermal injection (tattooing) of permanent pigments, 866 cleft palate splint, Studies in anatomy and repair of cleft palate 878 Miller Abbott tube, Cecostomy and, report on their combined use in preparation of obstructed large bowel for surgery 683

Intestine large, Evolution of adenomas of and their relation to carcinoma, 36 Carcinoma of colon, statistical analysis, 669 Experimental implantation of common bile duct into intestine, 697 obstruction of Penikellin in experimental summary of observations with reference to their clinical application, 753 Reoperative surgery for recurrent peptic ulcerations, 999 Cecostomy and Miller Abbott tube, report on their combined use in preparation of obstructed large bowel for surgery 683

Iodine, Thioracil and, preoperative management of thyrotoxic patient, 583

JACKSON Thomas J "Stonewall, Shenandoah tragedy 135

Jaw Cancellous bone grafts to, 553; Preservation of, function following surgery and trauma, 870 fractures of, Management of 973

Jejunum, Reoperative surgery for recurrent peptic ulcerations, 1020

Joint, Clinical experiences with use of penicillin treatment of infections involving bones and, 269

KIDNEY Studies on anuria, effect of infusion fluids and diuretics on anuria resulting from severe burns, 83 Blood supply of, suprarenal gland, and associated structures, 313 Fluid and electrolyte balance, 580 Complete occlusion of abdominal aorta, report of 3 patients diagnosed by aortography 610

Knee Extra-articular repair for ruptured collateral and cruciate ligaments, 330

Kyphoscoliosis, Transplantation of spinal cord, problem of, with cord signs, 460

LABOR, Adolescent primigravida, 662

Leg Leg 1 interruption of deep veins of lower extremities in prevention and treatment of thrombosis and embolism, 319, New operative treatment for elephantiasis, 412; M for amputations, 759 Radical amputations of extremities in treatment of cancer 105

Leg length inequality Supracardiac shortening of femur for 1087

Ligaments, collateral, cruciate Extra-articular repair for ruptured, 330

Liver Indications for portacaval anastomosis, analysis of cases, 645

Lungs, Axillary approach to Schede thoracoplasty 55 New technique for pulmonary segmental resection, its application in treatment of bronchiectasis, 37 cor 1137 Anomalies of pulmonary veins, surgical significance, 633 Treatment of chronic non-tuberculous pulmonary abscesses by high vacuum suction drainage 65

Luteinoma, Mucousoid tumors of ovary clinicopathologic survey with discussion of histogenesis and report of 3 cases, 23

Lymph nodes, New operative treatment for elephantiasis, 61

Apiration larynx of critical review of results of 30 aspirations, 1071

Lymphoma, M Significant, value of radical surgery in selected cases, 950

MANDIBLE Cancellous bone grafts to jaw 553; Preservation of jaw function following surgery and trauma, 870

Martin Randall H., photo, American surgeon, A.U.S., 932, 539

COLLECTIVE REVIEW

GAS GANGRENE

W. A. ALTEMEIER, M.D., F.A.C.S. and W. L. FURSTE, M.D. Cincinnati, Ohio

MANY of the great men of medicine have been interested in gas gangrene as a complication of wounds because of its spectacular nature, fulminating course, profound toxemia, mutilating effects, and high mortality. Hippocrates described very vividly a fulminating infection of the leg which appears to have been gas gangrene and Celsus also seemed to have recognized its occurrence. Thereafter the disease apparently was not recognized for a long time and Avicenna, Guy de Chauliac, J. de Vigo, and Ambrose Paré (12) did not refer to it although they observed many wounds. In 1745 Quesnay attributed the first exact observations on gas gangrene to Peyronnie, who described the subcutaneous emphysema, the erysipelatous color of the skin, and the rapidity of death. In 1746 Fabricius de Hilden also published one of the earliest clinical descriptions and expressed his belief that the principal cause of this terrible ill is some venomous humor which Nature has driven into these people. Later Dupuytren described a condition of spontaneous emphysema occurring in trauma and resulting in rapid decomposition of the injured part. In 1786 Thomas Kirkland recognized the disease and called it gangrene of the emphysematous type. Early in the nineteenth century Larrey, the leading surgeon of the Napoleonic wars, described the rapid progress of gangrene which spread from the injured limb in a few hours and often caused death in less than 10 hours. To prevent this complication of wounds which he called "traumatic gangrene" he advocated early amputation of mangled extremities. Boyer (1814)

Velpeau (1829), Martin de Bazas (1836) and Malgaigne all stressed its occurrence as a complication of fractured limbs. Chassaignac (1849-50) believed that certain gangrenes with emphysema had a poison far in excess of the mechanical injury and called it *empoisonnement traumatique*. Billroth thought that the decomposition of mortified elements, possibly by the action of some ferment, was the cause of this condition which he referred to as primary mephitic gangrene. Maisonneuve in 1853 named it *gangrene foudroyante* and at this time some believed the disease had its inception as a clinical entity. During the Crimean War, Pirogoff and Salleron wrote of this condition and in the Franco-Prussian War it was reported by Wyatt, Frery and Passow. However for some unexplained reason not a single case was recorded by Keen during the American Civil War.

Shortly thereafter during the bacteriological era, the bacterial cause of this disease was established and the more important causal bacteria were identified by various workers, Louis Pasteur discovering the *Vibrio septique*, Novy the *Clostridium oedematis*, and Welch the *Clostridium welchii*.

There is evidence that the incidence of gas gangrene has been significantly increased during more recent times, presumably because a high percentage of the wounds in modern wars has been produced by high explosive shells, bombs, and land mines. According to Zeissler, 100,000 German soldiers died of this complication during the first World War. In the more recent Ethiopian and Spanish Wars, gas gangrene was relatively infrequent, but with the advent of active fighting in

for neoplasm, hernioplasty (124), biliary tract operations (1) abortions (44) instrumental deliveries, hypodermic injections (81 119) and seemingly clean surgery, particularly amputations for arteriosclerotic or diabetic gangrene

Although it may occasionally follow quite trivial injuries it is most likely to develop in wounds with the following features

- 1 Extensive devitalization of muscles particularly in the extremities.
- 2 Interference of the main blood supply to a limb or muscle group produced by injury prolonged application of a tourniquet tight packing or application of constricting bandages, splints, or casts.
- 3 The presence of foreign bodies clothing or dirt deep in the tissues.
- 4 Delay in surgical treatment
- 5 Puncture wounds with considerable hemorrhage or retained foreign bodies (182)

Certain muscles derive their blood supply from one or two main sources and this is true particularly for the gluteus maximus, hamstring rectus femoris vastus intermedius and gastrocnemius muscles. Massive devitalization of tissue produced by any crushing lacerating or penetrating wound which impairs or destroys these sources of blood supply enhances the occurrence of gas gangrene Power has pointed out that the re-establishment of the collateral circulation of ischemic muscle appears to be extremely slow and that muscle deprived of its blood supply for 6 8 or more hours frequently dies. MacLennan (108) found that in 28 of 44 cases of gas gangrene in the Tripolitania and Tunisia campaigns a major artery had suffered severe trauma

Type of projectile. Trueta, Lenner and Mullally observed that the nature and form of the projectile producing a wound played an important etiological role Rifle, pistol and machine gun bullets, particularly those that retain their proper shape seldom produced this complication while bullets misshapened either deliberately or by ricochet were more prone to produce clostridial infections. Injuries caused by bombs shells, or trench mortar grenades were prone to precipitate gas gangrene because of the irregular shape of the wounds, the extensive damage to the soft tissues, and the impairment of both the local and general circulation

Improper surgical care Improper surgical care of wounds may be a very potent factor in the development of gas gangrene because of the resultant formation of devitalized tissue in a wound. The prolonged application of a tourniquet may produce ischemia and necrosis of muscle thereby

giving any bacteria that are present an excellent opportunity to proliferate (151) A delay in initial surgical care for the men wounded in skirmishes between patrols in Tripolitania and Tunisia resulted in an incidence approximately 4 times greater than that for those injured in pitched battle (106) Delayed definitive treatment may actually permit the inception of gas gangrene while inadequate débridement primary closure of incompletely débrided wounds, tight packing of wounds closure under tension and application of improperly fitting casts or splints may favor the development of devitalized tissue and gangrenous clostridial infections (68) Plaster-of-paris casts may be particularly dangerous when applied under conditions which do not permit close observation of the patient afterward and when the cast has not been bivalved or split to allow for subsequent swelling of the tissues (74)

BACTERIAL ETIOLOGY

Gas gangrene is a clinical entity of multiple bacterial etiology produced by a great variety of gas-producing anaerobic bacteria chiefly the *Clostridium welchii*, *Clostridium oedematiens*, *Clostridium septicum*, *Clostridium histolyticum* and *Clostridium sporogenes*. Other clostridia described include the *Clostridia fallax tertium*, *putrificum*, *aerofetidis bifementans capitovalis* and *sphenoides* (8 26 54, 76 107 123 167) The individual case usually presents a mixed bacterial flora and aerobic pathogenic cocci and bacilli have been found to coexist with the anaerobes in more than half of the cases. The different strains have varied symbiotic and synergistic relationships which are but little understood. The bacteria producing the initial infection in gas gangrene are but slightly proteolytic and much of the tissue destruction and digestion that follow the gaseous infiltration and edema is thought to be due to proteolytic commensals, the most frequent and active of these being the *Clostridium sporogenes* (40)

Trueta reported the relative incidence of anaerobic bacteria in cases of gas gangrene studied by various men as follows

	Welch and Sergius Per cent	McIntosh per cent	Henry per cent
<i>Clostridium welchii</i>	77	67 3	80
<i>Clostridium oedematiens</i>	34	4 0	10
<i>Clostridium sporogenes</i>	27	38 7	—
<i>Clostridium fallax</i>	16 5	—	6
<i>Clostridium septicum</i>	13	16 3	13

According to Bates the *Clostridium welchii* occurs in approximately 80 per cent of the cases of gas gangrene the *Clostridium septicum* in 10 per cent, and *Clostridium oedematiens* in 3 per cent.

Europe in 1939 and 1940, its incidence increased, varying between 0.7 and 1.8 per cent.

PREDISPOSING FACTORS

Location of the wound. There are many factors which have been found to predispose to the development of clostridial infections. The location of the wound is of considerable importance since the various tissues of the body are known to have different powers of local resistance and the resistance of these tissues also varies with their location. The muscular areas of the thigh, calf and buttock are especially susceptible while the face, scalp, back, and thorax are affected infrequently (2, 99, 107, 124, 168). In a series of 607 cases collected by Millar from civilian life between the beginning of the Post-Lester period and 1930 the known sites of injuries developing gas gangrene were the lower extremities in 47.6 per cent, the upper extremities in 22.6 per cent, undesignated extremities in 11.3 per cent, the trunk and genitalia in 16.3 per cent, and the head or neck in 2.4 per cent.

The legs have been most often affected because of their large masses of muscular tissue which are subject to traumatization and growth of the clostridia, their susceptibility to injury of the arterial circulation and the likelihood of contamination by dirt and fecal matter (86). All parts of a given region have not been equally susceptible. Trueta pointed out that gas gangrene developed in the thigh most commonly from wounds in the upper third, less often from wounds in the middle third and least often from wounds in the lower third. Furthermore it occurred more commonly in wounds of the front of the thigh. In the arm there appeared to be less distinction between one part and another.

Age. The highest incidence of gas gangrene has been in the age groups between 10 and 39 years, the ages that are commonly exposed to the physical hazards of life (124).

Sex. The ratio of males to females in civilian practice (124) was about 5.7 to 1.0 while in military practice the cases were confined almost entirely to males for obvious reasons.

Season. Maes found that gas gangrene occurred more frequently in the colder than in the warmer months of the year and he believed that clostridial contamination of wounds by woollen clothing worn more frequently in cooler months was the explanation.

In Millar's series, however, this variation according to season was not apparent, the incidence being approximately the same for the four seasons of the year.

Geographical location. Areas which have been repeatedly cultivated over several or more centuries have produced a higher incidence of gas gangrene than noncultivated areas. This was supported to a certain extent by MacLennan's observations upon the anaerobic bacterial flora of samples of soil taken from the African desert and from the cultivated environs of some coastal towns (107). MacLennan also pointed out that the incidence of gas gangrene increased from 3.4 per 1,000 wounded to approximately 6 or 7 per 1,000 wounded when the fighting moved from the Western Desert to the more cultivated areas of Tripolitania and Tunisia.

General physical condition. Reduction in the patient's general powers of resistance by shock, fatigue, exposure, continued pain, hunger, malnutrition, loss of blood, and certain metabolic diseases such as diabetes and arteriosclerosis has increased his susceptibility to clostridial infection (3, 43).

EXCITING FACTORS

Type of wound. Certain types of wounds, such as compound fractures, gunshot and high explosive wounds, fracture dislocations, extensive lacerations, or crushing injuries containing torn devitalized muscle and dirt have been particularly prone to develop gas gangrene (26, 145, 182). The presence of foreign bodies, such as dirt, gravel, clinders, bits of clothing or fragments of wood, metal or glass, has seemed to enhance the virulence of contaminating clostridia. This has been clearly demonstrated experimentally in a recent study of gas gangrene in animals by Altmeier and Furste (10) who found that the minimum lethal dose of a standardized strain of *Clostridium welchii* was decreased 1,000 times in the presence of devitalized muscle and 1,000,000 times in the presence of crushed muscle and dirt. In other words, it took only one-millionth as many bacteria to produce a fatal gangrenous infection in the presence of devitalized muscle and dirt as it did when bacteria were injected into healthy muscle.

The association of gas gangrene and fractures is well known. In the American Expeditionary Forces of the first World War there were 1,379 cases of gas gangrene among the 25,272 cases of fracture of bone, an incidence of 5.3 per cent (26). In Millar's series, 60.9 per cent of the cases collected from civilian life occurred in individuals with fractures.

Other forms of trauma that have precipitated this complication are cutaneous thermal burns (52, 124) and various operations including appendectomies, genitourinary operations, resections

ized by cholesterol it is similar to streptolysin O to which it is closely related antigenically

3. Eta toxin is a lethal toxin without necrotizing or hemolytic activity which has been differentiated from alpha toxin by discrepancies in the neutralizing values of sera as determined by necrotizing and lethal testing

4. Beta toxin is a thermolabile lethal and necrotizing toxin which can be recovered from the intestinal tract of lambs suffering from lamb dysentery

5. Gamma toxin is a lethal toxin without hemolytic or necrotizing power the existence of which has been inferred because of discrepancies between the neutralizing values of various specific sera when tested against corresponding filtrates

6. Delta toxin is lethal and hemolytic for the red cells of sheep, pigs, goats, and cows but does not affect human serum or manifest any necrotizing activity

7. Epsilon toxin is a lethal and necrotizing toxin which exists in two forms, thermostable and thermolabile. In its thermolabile form it has occurred in the intestinal contents of sheep suffering from lamb dysentery and infectious enterotoxemia, and the disease is almost certainly due to absorption of toxin from the alimentary canal

Recently MacFarlane and MacLennan (109) have described further activities of *Clostridium welchii* toxin which may be very significant. In observations made on muscle taken from the site of clinical infection or following the intramuscular injection of toxin in rabbits they obtained evidence of a marked increase of extractable fat in such muscles which was due perhaps to the release of intracellular lipoids. By the incubation of rabbit and human muscles with *Clostridium welchii* toxin and toxin neutralized by antitoxin they were also able to demonstrate that the toxin produced a friable mass of loose brittle fibers which they designated as collagenase activity. This activity was not demonstrated for the toxins of *Clostridia oedematis* and *septicum*. They believed that there were possibly two toxic factors involved in gas gangrene: one derived from the bacteria, which can be neutralized by antitoxin and another derived from disintegrating tissues which can be prevented from killing the patient only by surgical removal of the tissues concerned. Studies at Cincinnati in experimental gas gangrene have also been indicative of a secondary toxin arising from the disintegration of tissue. This hypothesis received some support from the observations that the anaerobic cellulitis due to *Clostridia welchii* and *welchii* infections of the brain and serous lined cavities (140) is not associ-

ated with the profound toxemia observed in cases of *Clostridium welchii* myositis. This naturally leads to the question of a possible relationship between the effects of a toxic destruction of muscle and those associated with its traumatic destruction. In both conditions there is circulatory failure, liability to renal involvement leading to uremia and perhaps fat embolism. In this connection Cooke *et al.* have described 2 fatal cases of gas gangrene which showed extensive fat embolism of the lung and other organs at autopsy. It would seem profitable to focus attention on the collagenase activity of the toxin of the *Clostridium welchii*.

The knowledge that the *Clostridium welchii* occurs frequently in wounds in which no symptom of gas gangrene is observed has led to the assumption by some that many of the *Clostridium welchii* strains are atoxic. Robertson and Keppie investigated 26 strains of the *Clostridium welchii* obtained from wounds with gas gangrene, wounds with clostridial infection but without symptoms of gas gangrene, and wounds without evidence of clostridial infection. Their studies indicated that all of the strains tested seemed to be of a basic toxicity sufficient to produce gas gangrene if the state of the wound was such as to permit their rapid proliferation and the evolution of toxins.

In a recent study at Cincinnati (111) the virulence of 15 strains of the *Clostridium welchii* isolated from dirt was determined quantitatively and compared with that of 25 strains isolated from wounds manifesting gas gangrene, localized clostridial infections, or nonspecific low grade infections. The results of this study were as follows:

1. The virulence of strains isolated from infected wounds for as long as 35 years was from 1,000 to 1,000,000 times greater than that of strains isolated from dirt, clothing, and soil.

2. The virulence of the types isolated from localized infections and low grade infections in some instances was as high as that of strains obtained from the fulminating cases.

3. There was no measurable correlation between the virulence of these strains for experimental animals in closed wounds containing crushed muscle and dirt and their relative ability to produce alpha toxin, theta toxin and hyaluronidase in vitro.

4. The virulence as determined by the crushed muscle and dirt technique did not correspond with that determined by the simple injection of bacteria.

After a study of more than 600 strains of the *Clostridium welchii* isolated from cases of abortion Butler (24) concluded that the strains caus-

It has become increasingly apparent that the relative incidence of the various clostridia in gas gangrene varies with the geographic location. In a carefully studied group of 146 cases of gas gangrene developing in war wounds in the Middle East (107) the incidence of the *Clostridium welchii* was much lower (56 per cent) than that given by other workers in Europe while that of the *Clostridium oedematiens* was much higher (37 per cent). The occurrence of other bacteria in this series of MacLennan is well illustrated in Tables I and II.

However in the more recent fighting in France MacLennan and Macfarlane (109) later found that the *Clostridium welchii* was the most common single anaerobe in infectious gangrene occurring in 24 of 27 cases studied by them and in more than 90 per cent of the German cases reported by captured German medical officers. They also believed that the anaerobic flora of the soil in Italy was very similar to that of Tunisia and Western Europe, and that approximately 60 per cent of the wounds contained clostridia, among which the *Clostridium welchii* and the *Clostridium sporogenes* were predominant.

Although the *Clostridia oedematiens*, septicæ and histolyticum are recognized as the most important agents in the production of gas gangrene (26) the fact remains that the *Clostridium welchii* is the principal cause being present either alone or in association with the other gas-producing anaerobes in from 56 to 100 per cent of the cases in the reported series.

Characteristics of the Clostridium welchii This organism, first isolated in 1892 from a cadaver by Welch and Nuttall, has acquired eleven synonyms (140) the most frequently used of which are *Bacillus perfringens*, *Clostridium welchii* and the gas bacillus. It is a short, thick, capsule-bearing bacillus with truncated ends and it is fairly ubiquitous in man's environment being commonly present in soil dust, sewage milk, water the intestinal and genital canals of man and animals, woolen clothing and fur of domestic animals.

TABLE I.—INCIDENCE IN PER CENT OF PATHOGENIC ANAEROBIC BACTERIA FOUND IN 146 CASES OF GAS GANGRENE.

Species	Incidence in per cent
<i>Clostridium welchii</i>	56
<i>Clostridium oedematiens</i>	37
<i>Clostridium septicum</i>	9
<i>Clostridium histolyticum</i>	6

<i>Clostridium sphenoides</i>	3
<i>Clostridium haustiforme</i>	3
<i>Clostridium tetanomorphum</i>	3

Being one of the most hardy of all anaerobes, its most important characteristics include the production of a large amount of gas and powerful toxins during growth. Hemolysins for the blood corpuscles of man, rabbits, dogs, pigeons, white mice, hogs, cattle, sheep, horses, guinea pigs, white rats, and hens are formed (26). In the guinea pig, rabbit, hen, and pigeon, the hemolysins dissolve out the hemoglobins, while in the other animals, the red cells are destroyed. The seven toxins which have been described are listed below but for practical purposes only the alpha, theta, and beta toxins need be considered since the existence of the others is based mainly upon inference (133, 167, 179).

1. Alpha toxin is a thermostable lecithinase which splits lecithin and the lecithin group of lecithoproteins into phosphocholine and a diglyceride (106). Because of this property it is hemolytic to the red cells of most experimental animals except the horse and goat, and its intravenous, intramuscular or intraperitoneal injection is lethal to mice, guinea pigs, rabbits, pigeons, and sheep. Animals surviving more than a few hours after the intravenous inoculation of this toxin may develop a hemolytic anemia with hemoglobinuria. Subcutaneous injections produce a characteristic necrotic lesion.

2. Theta toxin is a lethal toxin which is vigorously hemolytic for the red cells of most laboratory animals except those of the mouse. Being oxygen-labile, thermolabile, and readily neutral-

Kuklin	100

from various parts of a battleship by Endo was contaminated by pathogenic strains of the *Clostridium welchii* in 48.4 per cent of 31 samples in the first collection and 59.5 per cent in the second. The soil of countries that have been cultivated for centuries has always been heavily contaminated with clostridia. Recently Altmeier and Furste collected 15 samples of dirt from the major street intersections of Cincinnati and found that all samples contained viable spores of the *Clostridium welchii* as well as of other clostridia. MacLennan (107) found that *Clostridium welchii* was present in 22 of 26 samples obtained from cultivated areas of the African desert, in 6 of 24 samples from soiled areas, but in only 1 of 41 samples collected from unsoiled areas. Similar but less striking results were obtained with the other clostridia.

Wool clothing is an important source of clostridial contamination and the observations that the uniforms of wounded soldiers harbored the *Clostridium welchii* and other clostridia in a high percentage of instances (51, 107, 165) led to the assumption that this was principally the result of soil contamination. However reports by Gage Macs, and Altmeier (10) indicated that clothing made from wool naturally harbors the *Clostridium welchii* and other anaerobic gas producing bacteria.

Other less common sources of contamination have been unsterile and imperfectly sterilized dressings and instruments (40, 158) the unprepared skin of the abdominal wall (152) and even the ice used for refrigeration anesthesia (92).

Incidence In view of its widespread distribution, the contamination of a considerable proportion of open wounds of violence is not surprising. Recent studies of the bacterial flora of various types of wounds are summarized in the following table which shows that the presence of the *Clostridium welchii* varied between 3.8 and 39.4 per cent. The average incidence of contamination in collected series of 3,027 wounds of violence both civilian and military was 14.7 per cent.

CLOSTRIDIAL INFECTION

Incidence In contrast to the relatively high incidence of contamination, the development of clinical gas gangrene in wounds is relatively infrequent. Its incidence has varied between 0.3 and 5.26 per cent in the following summary of collected series comprising 187,936 major open wounds, the average being 1.76 per cent.

This is especially remarkable since there is often no appreciable difference between the bacterial flora of the wounds developing gas gangrene and

TABLE IV — THE INCIDENCE OF THE CONTAMINATION OF WOUNDS OF VIOLENCE WITH THE *CLOSTRIDIUM WELCHII*

Author	No. of cases	N. of wounds contaminated	Percentage of cases contaminated

of those that do not (54). This brings up the very challenging question as to why only a small fraction of the wounds contaminated by clostridia develop gas gangrene.

According to Power the answer undoubtedly is that only 0.33 per cent of all the wounds undergo

TABLE V — THE INCIDENCE OF GAS GANGRENE IN WOUNDS OF VIOLENCE

ing severe infections differed both in regard to growth characteristics and to the amount of capsular material they produced in broth.

Woods and Fein studied the metabolism of amino acids in one strain of the gas bacillus, and, found that it attacked only 5 of 21 commoner amino acids which they investigated these acids included serine, cystine, threonine and arginine.

Observations upon animals infected with pure cultures of the *Clostridium welchii* have thrown much light on the pathogenesis of gas gangrene. The injection of large quantities of washed bacilli failed to produce gas gangrene in animals unless relatively large amounts were used. Characteristic lesions, however, were produced readily if a slight injury to the muscles preceded the injection of bacteria (10 25 26 147 167). In the presence of devitalized muscle the inoculation of a virulent culture of *Clostridium welchii* is typically followed by local swelling and induration within from 4 to 6 hours, which increases rapidly. Crepitation of ten becomes perceptible within 6 or 8 hours. The swelling is caused chiefly by edema, and to a lesser extent by infiltration of gas. The symptoms of intoxication that develop include extreme rapidity of the pulse and respiration, prostration, slight convulsions, and paralysis of the bowel. Before death, the animal has paralysis of its hind legs and convulsive contractions.

Characteristics of the Clostridium septicum This organism, originally described by Pasteur and Jonbert in 1877 normally lives in the soil and is a nonproteolytic very saccharolytic bacillus which produces powerful exotoxins including a hemolytic and a hemagglutinin. It produces less gas than the *Clostridium welchii* and an edema which, although highly hemorrhagic is soft compressible, and less extensive and gelatinous than that produced by the *Clostridium oedematiens*. Small vesicles containing serosanguineous fluid appear on the skin. The muscles infected by this organism are rendered soft and intensely red during the first few hours. It hemolyzes the red corpuscles of the guinea pig, rabbit, sheep, goat, and man (26). The pathogenicity of different strains varies considerably. Areas of swelling and induration develop fairly rapidly in rabbits and guinea pigs after the injection of the *Clostridium septicum* but they are never as extensive as those produced by the *Clostridium welchii*.

The studies of Bernheimer suggest that the hemolytic and lethal actions of crude toxin are either functions of a single substance or of two substances having a similar physical chemical and antigenic property.

Characteristics of the Clostridium oedematiens. This organism was probably first discovered by Novy in 1894 in a study of "malignant edema" in guinea pigs. The bacterium lives in the soil and produces a highly aggressive exotoxin which destroys the red corpuscles of man, sheep and guinea pigs (26). The organism is saccharolytic and produces little or no gas. Apparently it does not invade the tissues and hence, like the *Clostridium tetani* and the *Bacillus diphtheriae*, its poisonous effects are due entirely to its toxin (167) which is highly invasive and kills animals within 48 hours after intravenous injection.

The lesions produced by different strains of the *Clostridium oedematiens* vary according to their powers of toxin production. The intramuscular inoculation of a toxin producing strain is followed quickly by marked swelling of the limb which increases by the hour. As the firm elastic edema extends upon the abdomen, the thigh becomes cold and the skin pale and bluish. The muscles at the site of injection become congested and infiltrated with a gelatinous, deep pink fluid and many fine gas bubbles, but no putrid odor develops. Subcutaneous injection produces a similar lesion with a very thick, hardlike edema infiltrating the subcutaneous connective tissue for a depth of from 3 to 4 cm.

Characteristics of the Clostridium histolyticum. This organism, the most proteolytic of all the anaerobes, is pathogenic to varying degrees for all laboratory animals, including guinea pigs, rabbits, white mice, and rats (26). A guinea pig will die several minutes after an intravenous injection of from 1 to 2 c.c. of a 24 hour culture, and an intraperitoneal injection is lethal in the same dose. Intramuscular injection is followed immediately by violent tetany of the muscles about the head and neck and within several hours by local swelling and redness of the skin. A hemorrhagic layer develops in the subcutaneous connective tissue and the subcutaneous and perimuscular connective tissues undergo rapid digestion. As the process continues for several or more hours, the digestion of the perimuscular connective tissue becomes more evident and the muscles and the muscular bundles become dissociated and liquefied.

The *Clostridium histolyticum*, as well as the *Clostridium fallax* and *Clostridium sporogenes*, does not seem to be sufficiently aggressive to produce gas gangrene clinically by itself.

CLOSTRIDIAL CONTAMINATION OF WOUNDS

Sources It has been established that the *Clostridium welchii* is practically ubiquitous in the human environment. Even the dust collected

it is palpable. The accumulative effect of this vicious circle may cause the infection to be well advanced in 2 hours, and has been known to produce death from massive gas gangrene of an entire limb in less than 30 hours.

The anatomical picture of special gas gangrene infections may be so typical that conclusions as to the causal organisms may be possible. In the usual case of clostridial myositis caused by the *Clostridium welchii*, the lesion occurs most frequently in the thigh particularly in the upper anterior aspect, as an emphysematous gangrene that spreads, in some cases very extensively from the initial local focus. The wound is very dirty and exudes a thin, dark, evil smelling discharge containing bubbles of gas. The edges of the wound are dark and often black and the surrounding skin is tense swollen, and pallid but gradually assumes a yellowish blue or green color and still later presents areas of necrosis. In clostridial myositis caused by the *Clostridium oedematiens* alone or in combination with other bacteria the most characteristic feature is the absence of gas with widespread and rapidly progressive gelatinous edema immediate and severe general intoxication, and a time lag of 48 hours or more before the appearance of gangrene. The cellular spaces and subcutaneous tissues are distended by a clear gelatinous edema and the muscles are dark red or asphery in color.

SYMPTOMS AND SIGNS

The incubation period between the injury and the onset of gas gangrene varies between a few hours and 4 or more days. Lazarus and Cruickshank stated that while the usual incubation period varied from 1 to 6 or 7 days, the average being 3 days, it has been known to be as short as a few hours after operation and as long as 10 years after inoculation. In the experience of Neel and Cole in the Pacific area it varied from 1½ to 5 days the average being 2.35 days. MacLennan (108) reported an average incubation period of 23 hours for the *Clostridium welchii*, 48 hours or more for the *Clostridium oedematiens* (with an average of 5½ days) and 3 days for the *Clostridium septicum*. Although the incubation period may be as short as 6 hours after wounding the chief clinical manifestations usually develop on the second day.

Pain is nearly always the earliest symptom (30, 54, 167, 21, 108). Although it may be due in part to the effects of injury it is caused principally by the rapid infiltration of the tissues by fluid and gas. In some instances it has been described at first as a sensation of heaviness or tension and later as a burning but rarely a throbbing pain.

In virulent cases the initial symptom has usually been spontaneous pain or a sudden increase in the intensity of pre-existing pain which appeared within 18 to 24 hours after the injury and which was followed shortly by a distinct and rapidly developing distention of the traumatized tissues. Later the pain may disappear and in the overwhelming toxic forms complete absence of pain may be characteristic.

Rapid pulse. An alarming rapidity and feebleness of the pulse soon follows the onset of pain which is out of all proportion to the temperature (22, 30, 54). This may become increasingly apparent and progress to circulatory collapse which may be abrupt, progressive, and severe. As the pulse rate becomes increasingly rapid, the amplitude becomes steadily smaller. Early the blood pressure has been described as slightly elevated (167) but later it may become significantly low (108).

Temperature. The degree of fever varies considerably but frequently it is less than 101° F. It is not a reliable index of the severity and extent of the infectious process, but it may indicate the prognosis, for a low temperature with rapid pulse suggests a grave outlook. In civilian practice this is not always true, since we have seen severe proved cases with a temperature of 105° F or greater. In the mildest type of clostridial infection clostridial cellulitis, there often is considerable rise in the temperature but the pulse rate shows a corresponding increase.

General appearance. Early in the course of the disease the patient may develop a peculiar grayish pallor, listlessness, weakness, profuse sweating, prostration, breathlessness, and dilated pupils. The usual malar flush associated with pyogenic infections is replaced by a striking pallor (54) and an extremely worn or strained expression of the face (99). The pallor may be succeeded by a yellowish or icteric tint of the skin and sclerae. MacLennan (107) has emphasized that the profound shock and toxemia developing in gas gangrene are relatively uninfluenced by transfusions of blood.

Mental state. This is one of apathy and indifference, the patient being quite conscious but usually unaware of the seriousness of his condition. The more common central nervous system manifestations may be divided into those of hyporritability and hyperirritability. The former are more common with the wet type of gas gangrene while the latter are more frequently seen in the crepitant form (30). Stupor, delirium and coma may occur late.

Gastrointestinal symptoms. Anorexia is a fairly constant finding and vomiting is not an uncommon

sufficient arterial damage to produce an adequate amount of ischemic muscle in which the clostridia can multiply. Although this factor is of importance, the answer does not appear to us to be this simple. Fleming pointed out that the infecting agent has often acquired increased virulence in passing from one individual to another in civilian practice, whereas the virulence of the agents infecting war wounds has been more than likely attenuated by the unfavorable surroundings under which they existed.

PATHOLOGY

There is still considerable confusion regarding the classification and interpretation of the pathologic changes in clostridial infection. A large number of descriptive terms has been applied to it, such as subcutaneous emphysema, primary nephritic gangrene, traumatic gangrene, bronze crystal, spontaneous emphysema, empoisonnement traumatique, and gangrene foudroyante. More recently terms such as clostridial myositis, anaerobic cellulitis, anaerobic toxemia, and toxic edema have appeared.

The term gas gangrene is inadequate and undesirable in many respects and the following classification is more desirable:

1 Clostridial myositis

a. Spreading or diffuse (gas gangrene)

- 1 Crepitant
- 2 Noncrepitant or edematous
- 3 Anaerobic toxemia

b. Localized myositis

- 1 Crepitant
- 2 Noncrepitant

2 Clostridial cellulitis (crepitant phlegmon or anaerobic cellulitis)

Clostridial myositis of the spreading or diffuse type represents true gas gangrene and it may be manifested clinically as the crepitant type, the noncrepitant or edematous type, the mixed type, or the profound toxic type. Because of its mild and self limiting nature, localized clostridial myositis should not be considered as gas gangrene. Diffuse clostridial myositis is essentially an affection of the muscles, and the connective tissues may be comparatively little affected at first. The clinical and pathological pictures presented by this infection differ markedly in long and in segmented muscles (167) the spread, rapidity of evolution, and gravity of the process all being greater in the former. Three distinct zones in these lesions have been described by Trueta: these are

- 1 A central or dead zone which consists of disintegrated muscle destroyed by trauma, organized clot and a vast number of organisms.

- 2 A second or dying zone which contains devitalized muscle fibers covered by masses of bacteria and the products of infection. Their anatomical arrangement remains undisturbed although the fibers became separated by an exudate which is or is not packed with leucocytes, according to the type of infection. Local leucocytosis usually is associated with mixed infections.

- 3 A third or normal zone in which the muscle is normal, except for some cellular infiltration.

The causal bacteria are found more often in the lymph surrounding the muscle fibers than in the fibers themselves, and their spread is in a longitudinal direction rather than a transverse one. It is believed by some that the infection extends rapidly through the damaged muscle to the area where the circulation is still intact and the muscle fibers are normal, where it is temporarily checked. Thus, although the tissues of the first and second zones are quickly destroyed by the combined effect of the trauma and infection, the vitality of the third zone may temporarily prevent further spread of the process and permit successful treatment. Others believe that the process spreads primarily in the connective tissue in the intermuscular septa and surrounding veins and nerves (139). The studies of McNee and Dunn on the microscopic appearance of the advancing edge indicated that the bacilli spread up and down the muscle in the interstitial tissues, preceded by the exudation of a toxic fluid which separated the muscle fibers from the interstitial tissue and killed them, permitting their invasion by the bacteria. Krupp and Smith working with Reed and Orr confirmed the tendency of gas gangrene to spread in loose connective tissue and along the fascial planes. They also concluded that the toxins of the *Clostridium welchii* inhibited the accumulation and phagocytic action of leucocytes and other phagocytic cells.

As gas and edema accumulate in spaces confined by aponeurosis and stretched in elastic skin, a great increase of pressure occurs in the tissues which is sufficient to produce further necrosis of muscles and compression of the lymphatics, veins, and arteries even as large as the femoral. This opens the malignant phase of the infection, and the successive stages of muscle disintegration and bacterial invasion follow one another with great rapidity involving not only a single muscle but a whole group and often an entire limb. The muscles, at first hemorrhagic and friable, contract and soon exude a watery blood stained and often brown, foul discharge containing bubbles of gas. The infiltration of the muscles and the intermuscular planes extends well above the area in which

welchii obtained from smears cultures or tissue by Altmeier (8) using a modification of the stormy fermentation of milk by the *Clostridium welchii* by Nagler Crook Hayward Weed and Minton using the Nagler reaction for the *Clostridium welchii* and by Gordon and McCleod using heated blood agar plates containing benzidine for the rapid identification of the *Clostridium oedematis*. Reed and Orr (148) also collected a series of diagnostic biochemical reactions which were generally sufficient to differentiate the various species within 24 hours. While these various tests and considerably in early diagnosis they all have definite limitations. They do not distinguish the virulent and toxigenic strains from the nonpathogenic ones (104) and it must be kept in mind that these anaerobes have been frequently isolated from wounds not affected with gas gangrene.

Serum roentgenograms taken for gas in the soft tissues have been of practical value in the detection of early or incipient gas gangrene permitting a positive diagnosis 24 or more hours earlier than possible by the clinical findings alone (10 13 167). Films taken at intervals of from 2 to 12 hours may aid in the differentiation of gas due to the clostridia from that due to mechanical causes. If the gas increases in amount or presents a linear spread in the muscle planes, a diagnosis of gas gangrene can be made.

It must be kept in mind that valuable time may be lost in awaiting results of various diagnostic tests during which irreversible changes may occur in the tissues. For this reason it has been more practical in our experience to explore surgically and without delay any wound in which the presence of clostridial myositis is suspected. This plan permits earlier radical surgery when necessary and thereby the most effective method of control of the process.

DIFFERENTIAL DIAGNOSIS

Anaerobic cellulitis, streptococcal myositis, and hemolytic streptococcal gangrene must be considered in the differential diagnosis of gas gangrene. Of lesser importance are traumatic emphysema magnesiumous pneumogranuloma staphylococcal acute infectious gangrene, and gangrene caused by the accidental injection of some foreign agent.

Anaerobic or clostridial cellulitis is a crepitant septic process of the epifascial retroperitoneal, or other connective tissues which usually have been de-vitalized by trauma. There is usually no extensive invasion of living muscle as in true gas gangrene. It is most commonly seen in extensive lacerations of soft tissues other than muscle, the anaerobes multiplying freely in necrotic debris. The incubation

period of anaerobic cellulitis is usually 3 or 4 days and the onset is more gradual than that of true gas gangrene. Systemic effects may be slight unless the wound is also very septic, and this relative mildness of the general reaction is helpful in distinguishing between it and true gas gangrene. However anaerobic or clostridial cellulitis is not a condition to be regarded lightly. The spread of infection in the tissue spaces may be rapid and extensive and necessitate radical surgical drainage even within a few hours.

Streptococcal myositis In this condition there is a massive infection of muscle together with discoloration edema, serous exudate gas formation local pain and generalized toxemia. Neglected cases may progress to a true gangrene of muscle. The chief points of differentiation between it and clostridial myositis are (1) its more pronounced and extensive cutaneous erythema (2) its involvement of muscle which although edematous and discolored is still alive and reactive to stimuli (3) its different odor and (4) the microscopic appearance of a muscle smear stained by Gram's method which reveals no gram positive bacilli but vast numbers of streptococci among masses of pus cells.

Hemolytic streptococcal gangrene occasionally follows some relatively minor operative procedure or injury. The lesion is essentially an epifascial spreading subcutaneous gangrene with thrombosis of the nutrient vessels and resultant slough of the overlying skin. It usually develops in the extremities although the perineum face and other parts of the body may be involved. It is characterized by the onset of pain and marked swelling at the site of the wound, chills elevation of the temperature to from 101° to 104° F. rapid pulse toxemia prostration and a rapidly spreading painful cellulitis which undergoes hollous formation and a peculiar patchy and extending necrosis. Hemolytic streptococci are found in the subcutaneous gangrene and bullae often in pure culture.

Acute infectious staphylococcal gangrene may occasionally simulate gas gangrene. Morrison reported such a case in a 5½ year old boy who developed a rapidly spreading cellulitis with pain swelling hrawny induration patchy discoloration of the skin and elevation of temperature to 105° F. 3 days after injury. No organism other than the *Staphylococcus aureus* was demonstrated on aerobic and anaerobic culture of the pus obtained by multiple incisions in the involved tissues.

Crepitation of tissues not produced by bacteria Cases in which air has been sucked into tissues by penetrating or perforating missiles have been confused with true gas gangrene in some instances.

mon symptom. The tongue very quickly becomes dry and coated.

Appearance of the local lesion. The skin overlying the lesion is at first white and tense. There is usually an irritating dirty brownish watery discharge from the wound with a peculiar foul odor. As the swelling increases, the overlying skin becomes dusky and bronzed or khaki-colored in appearance (54). If further discoloration occurs, vesicles filled with dark red fluid appear on the cutaneous surface and later coalesce as the lymphatics and venous channels become blocked. The changes in color of the skin appear earlier in the more superficial and confined infections than in the deep highly invasive types. The distal portion of the limb becomes edematous, engorged, discolored, cold and finally gangrenous. If the patient lives long enough, sloughing may occur. The area of wet gangrene of the skin is always much less than that of the underlying muscle. The edema that occurs in gas gangrene is an integral part of the picture. With certain of the bacteria, such as the *Clostridium oedematiens*, the swelling is extreme and causes the skin to become tense and marblelike in appearance. The appearance of the muscles with their grayish or black sloughing surface is a striking feature. They may be so swollen that they herniate out of the wounds (55). The necrotic muscle does not contract or bleed when cut, and usually presents a darkened color with few gas bubbles in the wound and in the intermuscular septa.

In discussing battle casualties in a South Pacific Evacuation Hospital, Potts pointed out that bubbling of small amounts of gas from an infected wound does not necessarily mean gas gangrene in the ordinarily accepted sense of the term, but a less virulent localized area of myositis in the absence of the well recognized clinical picture. In the cases of clostridial myositis seen by Ross and Ryan in the Owen Stanley and Buna-Gona Campaign, wide variation in clinical types was seen, ranging from the classic fulminating infection with the associated general signs to a local abscess around a retained missile. These latter cases were not gas gangrene but localized areas of clostridial myositis.

Laboratory examinations. In many instances a marked reduction in the number of red corpuscles occurs with counts ranging between 1 and 2 million cells per cubic millimeter. The low red blood counts and hemoglobin levels as low as from 30 to 40 per cent are due to the hemolytic anemia and are probably the most striking laboratory findings. The leucocyte count usually does not exceed 12,000 or 15,000 cells per cubic millimeter but in

civilian practice it may occasionally be quite high. In the experience of Nikol'skaya severe infections produced by the *Clostridium welchii* in association with the *Clostridium oedematiens* were often associated with a leucopenia—a definite lymphopenia, but rarely a leucocytosis.

According to Trueta, there may be an immediate deterioration of the liver function with consequent acidosis, which was first noticed by Sir Almroth Wright during the first World War and confirmed by Marquid, Clogne, and Didier in France. How far the acidosis contributes to a fatal issue is not known, but the prognosis is related to its intensity.

Positive blood cultures are rarely found (26, 54) but may occur in the initial stages of the fulminating *Clostridium welchii* toxemia described by Trueta. In infections produced by the *Clostridium oedematiens*, rises in hemoglobin levels to as much as 130 per cent have been reported if the edema became extensive and much oozing occurred.

DIAGNOSIS

It must be emphasized that this disease is a clinical concept which has usually been recognized by the clinical appearance of the patient and his lesion in its obvious, far advanced, and often in reversible stages. Continued pain at the site of a wound containing devitalized muscle, a rapid and easily compressible pulse, varying degrees of fever, toxemia in association with spreading edema, a thin brown water malodorous discharge, crepitation, herniation of discolored muscle which does not bleed or contract, and typical discoloration of the skin in the region of the wound are relatively late symptoms and signs that strongly suggest the nature of the lesion, even to the novice. Repeated questioning and close observation of wounded patients unquestionably are of value, and the old principle of promptly inspecting the wound in the presence of unexplained fever or pain has been particularly valuable in the earlier recognition of the process. Infiltrating gas may be detected early by the experienced observer through auscultatory percussion, but usually the presence of casts, splints, or large dressings obscures the wound and makes diagnosis difficult and the interpretation of local signs indirect.

Considerable investigative work has been carried out to facilitate earlier diagnosis, principally through the development of methods for the rapid identification of the clostridia *welchii* and *oedematiens*, and other anaerobes associated with gangrene. Methods have been developed and adapted to clinical use by Butler (23) using the demonstration of stained capsules for the *Clostridium*

Clinical examination of these patients who do not show the signs of severe toxemia reveals palpable crepitation in the tissues but roentgenological examinations usually show that collections of air lie along the course of the wound rather than in the planes of the tissue.

Rubenstein, Tabernhaw and Daniels reported 3 cases with subcutaneous crepitant tumor masses about lacerations of the hand in patients who had handled an alloy containing 90 per cent of finely powdered magnesium.

An extremely rare condition which may be confused with gas gangrene is that caused by the accidental injection of benzene. Schreus reported on a series of 15 patients who developed crepitant necrosis of muscle a few hours after injection into the pectoralis muscle of material thought to be typhoid vaccine but later proved to be benzene. No bacteria were found in the exudate.

TREATMENT

Prophylaxis. Early and adequate surgery is still the most effective means of preventing gas gangrene since it not only eliminates the conditions necessary for the propagation of the bacteria but also removes most of the contaminating bacteria (3, 13, 21, 25, 29, 93, 135, 176). Adequate surgery implies early meticulous excision of all dead and devitalized tissues, removal of dirt, clothing and other foreign material from the wound, preservation of the blood supply, relief of tension, and sufficient drainage when indicated. In this instance as always it must be remembered that débridement has replaced the use of antiseptics in the prevention of wound infections (2). The use of postoperative immobilization and the avoidance of tension constricting or malfitting casts and dressings which might produce ischemia and further devitalization of tissue are also integral parts of prophylactic surgical treatment. Any "packing" of open wounds must be done loosely as tight packing may result in devitalization of tissues from pressure and inadequate drainage.

Although there is considerable evidence that the prophylactic administration of gas gangrene antitoxin is of little practical value in the prevention of clinical gas gangrene it has been given almost routinely at the time of injury (3, 41, 48, 51, 62, 63, 83, 93, 110, 121, 171, 176). English surgeons (49) however have strongly advocated the prophylactic administration of antitoxin to injured patients in whom there is any reason to anticipate gas gangrene as a likely complication. In 1944 the preparations recommended by the British contained 22,500 international units of polyvalent antitoxin including 9,000 units of *Clostridium*

welchii antitoxin, 4,500 units of *Clostridium septicum* antitoxin and 9,000 units of *Clostridium oedematis* antitoxin in each ampule. The surgeons stated that clinical judgment of the local and general condition should determine whether the minimum prophylactic dose is likely to suffice or if the dose should be repeated or increased. Hall (65, 66) also stated that there was no reason to doubt the prophylactic value of 7 American gas gangrene antitoxins against the anaerobic infections for which they were intended. He believed that when prompt adequate surgery is possible, gas gangrene may be prevented by this method alone and that the prophylactic use of serum may augment the effectiveness of both early and delayed surgery. He reported that 6 of the commercial antitoxins available were bivalent, containing *Clostridium welchii* and *Clostridium septicum* antitoxins only. Those who question the effectiveness of antitoxin as a prophylactic agent state that gas gangrene is not too well defined as a clinical disease which has a multiple etiology. Since a large variety of gas forming anaerobic bacteria has been identified with this infection, either in pure or mixed culture, it seems rational to use the pentavalent antitoxin rather than any of the lower valent antitoxins. It seems well established that the prophylactic use of antitoxin can in no way take the place of adequate surgery.

At first chemotherapy appeared to be effective in the prevention of gas gangrene, but subsequent experience has shown the great limitations of each of the available agents. Penicillin has been by far the most effective (9, 10, 55) and streptomycin the least. Cutler and Sandusky reported 5 cases treated with penicillin immediately following primary débridement in which gas gangrene developed. They concluded that proper surgical débridement is the major factor in both the prophylaxis and therapeutics of this infection. Similar experiences were reported by Patterson, Keating, and Clegg and by Conway.

In a series of investigations on experimental gas gangrene in guinea pigs produced by the *Clostridium welchii* of standardized virulence, Altmeier and Furste (10) were unable to demonstrate any prophylactic effect of penicillin when a dose of 2,000 units per kilogram per 24 hours was given in divided doses every 3 hours and continued for 4 days. This dose corresponded to one of approximately 17,500 units every 3 hours for an adult male. When the dose was increased to 8,000 units per kilogram per 24 hours, corresponding to an adult daily dose of 70,000 units every 3 hours, the survival time was definitely lengthened and 16 per cent of the animals survived. When the dose was

the mainstay of postoperative management. Plasma has usually been reserved for the correction of persistent hemocoagulation in selected cases of the "wet" types of clostridial infection.

From an analysis of available information the effective methods of treatment for established clostridial myositis or true gas gangrene may be summarized as follows:

- 1 Radical surgery as soon after diagnosis as possible consisting of multiple incisions for decompression and drainage of the fascial compartments, excision of the involved muscles, or open amputation when necessary, followed by adequate immobilization of the affected part.

- 2 Administration of polyvalent gas gangrene antitoxin before and after surgery—50,000 units every 4 or 6 hours as indicated to aid in the control of the toxemia.

- 3 The injection of penicillin parenterally in very large doses up to 1,000,000 or more units every 3 hours before and after surgery to aid in the control of the infection. After its obvious control the dose of penicillin may be gradually reduced.

- 4 Complete bacteriological diagnosis.

- 5 Sulfadiazine or streptomycin may be used for the control of secondary infection if indicated.

- 6 Adequate supportive therapy including frequent transfusions of whole blood, relief of pain, maintenance of the fluid and electrolyte balance and control of acidosis.

- 7 The topical use of zinc peroxide ointment on wound surfaces after radical surgery.

- 8 Secondary operative procedures to facilitate healing of the wound or function of the extremity as indicated.

SUMMARY

A survey of the literature reveals that gas gangrene is a very old disease of multiple bacterial etiology and variable clinical picture which occurs as a spectacular and destructive complication in an average of 1.76 per cent of all contaminated wounds of violence. Recent studies have increased our knowledge regarding the predisposing and exciting etiological factors of this disease but the precipitating factor that sets off the infection and explains the discrepancy between the low incidence of infection and high incidence of clostridial contamination in similar wounds is still unknown. The steadily increasing reservoir of information which is being accumulated regarding the characteristics, toxins, and virulence of the various clostridia is contributing to a better understanding of the pathogenesis of this disease. Recent evidence suggests that the profound toxemia associated with this condition is complex being caused not only by the specific toxins and enzymes

produced by the bacteria but also by nonspecific toxin products arising from the degenerating tissue in the area of infection. It has been relatively easy to protect animals from the injection of one or more minimum lethal doses of toxin by the administration of antitoxin or by immunization with toxoid. On the other hand the protection afforded by antitoxin or toxoid has been only partial against one or more minimum lethal doses of virulent bacteria.

The various clinical and pathological pictures associated with this condition in its advanced stages have been well established but considerable difficulty is still experienced in the early recognition of the process. The intelligent use of serial roentgenograms has been of value but better methods of early diagnosis are still needed. Numerous diagnostic tests have been devised recently to facilitate an early and positive diagnosis. Although some of these are of value definite limitations and even danger may attend their clinical use.

Early and adequate surgery is still the best method of treatment for either the prevention or control of gas gangrene. Chemotherapy has been shown to be a valuable adjunct to surgery and penicillin in massive doses appears to be the agent of choice. The effectiveness of serotherapy both prophylactically and therapeutically is still disputed but the evidence indicates that the early administration of the polyvalent type aids in the control of the toxemia when used in conjunction with the necessary surgery.

The preliminary results of investigations with toxoid immunization of experimental animals are encouraging and suggest that effective prevention of this condition by the use of toxoid is a definite possibility.

(120) per day. In their studies of experimental gas gangrene Altemeier and Furate (10) found that average doses had no measurable effect but that large doses corresponding to 8,000,000 or more units per day in an adult man had a definite therapeutic effect. Without surgery, however, discontinuation of penicillin was followed by spread of the lesion and ultimate death. These experiments indicated that penicillin when used in large doses, is a valuable adjunct to adequate surgery in the treatment of established gas gangrene because it limited the spread of the lesion, prolonged the period during which surgical decompensation and excision of involved muscles could be done successfully, and reduced the mortality. A dose of 1,000,000 units or more every 3 hours is suggested for clinical use in the management of severe established infections. Apparently such large doses may be given without toxic effect. Keefer and Anderson pointed out that the maximum dose of penicillin that can be given to man has not been determined as yet and that doses as large as 100,000,000 units a day have been given without ill effect (85).

On the other hand, Odom and Conway concluded that penicillin in much smaller doses was of little or no value and the former believed that its sole value lay in controlling secondary infection.

Early experiences with the sulfonamides led to the recommendation of their use in the treatment of gas gangrene (13, 33, 39, 64, 76, 77, 107, 137, 160) but the recent trend has been away from the use of sulfonamides for gas gangrene itself (171). Jeffrey (79) found no evidence that sulfanilamide, alone and without operation, saved any patient from true gas gangrene. Langley and Winkelstein, who studied 96 cases treated at an evacuation hospital in Northern France during 1944, believed that sulfonamides had little or no effect on the course of gas gangrene and Conway concluded that there was no evidence that sulfadiazine given in adequate amounts produced any significant change in the general condition of patients.

A variety of preparations have been used for topical application on surgical wounds resulting from the treatment of gas gangrene. The use of activated zinc peroxide as a watery suspension (120) or ointment (6, 32, 64, 75, 101, 120, 150) seems to be the treatment of choice. Effective use, however, depends primarily upon correct application at intervals of from 1 to 2 days with intimate contact of the tissues with the zinc peroxide preparation, adequate hydration produced by a layer of wet absorbent cotton, prevention of the escape of liberated oxygen and moisture by a layer of ointment gauze and a mild compression dressing.

The value of roentgen irradiation as a method of therapy in true gas gangrene is still uncertain. Kelly has been its most enthusiastic proponent and in his opinion the results of its use have far surpassed those obtained with serum, debridement, and amputation. He has been inclined to regard roentgen therapy as a specific in gas gangrene recovery following its use in all cases if it was employed during the first 24 hours. McMillan was equally enthusiastic, he reported a mortality of 14.9 per cent among the 416 cases in which roentgen therapy had been used. Cantrell (27, 28) recently deplored the lack of appreciation by physicians of the value of treatment of this type of infection with the roentgen ray. He believed that debridement or other surgical procedures in the acute phase of an already established gas bacillus infection was not indicated when roentgen therapy was available. In view of the fact that serum and surgery were employed in some of the cases, it is difficult to say whether the recovery of 4 patients was due to roentgen therapy or to serum therapy and surgery and the same difficulty applies to the reports of Faust and Turner.

Unfortunately these results have not been substantiated by other clinical investigators, and attempts to reproduce them in animal experiments have failed. Cubbins, Callahan and Scuderi were of the opinion that the roentgen irradiation of gas bacillus infection had little if any value and they saw no reason for considering it as a method of treatment. In 8 cases of proved gas infection which were treated by roentgen irradiation and without surgery or antitoxin there were 8 deaths. Cozen (37, 38) also thought that it is unwise to place complete reliance on roentgen therapy for gas gangrene. In his 8 cases which were treated without operation or antitoxin but with roentgen irradiation, there were 8 deaths. Coleman and Bennett using roentgen therapy alone in 14 cases had 4 recoveries and 10 deaths. In experimentally produced gas gangrene Caldwell and Sewell, Dowdy and Vincent as well as Kelly and his associates, have been unable to demonstrate any measurable beneficial effect from roentgen therapy.

The general supportive measures of value in the management of gas gangrene include frequent or daily blood transfusions, maintenance of the fluid and electrolyte balance (6, 13, 82), adequate immobilization of the infected and injured parts (6, 167), oxygen therapy, and the relief of pain. Frequent blood transfusions help to correct the profound anemia with which this condition is frequently associated (6, 13, 32, 172). Conway found that the frequent transfusions of whole blood were

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

HEAD

Kazanjian V. H., and Webster R. C.: The Treatment of Extensive Losses of the Scalp. *Plast Reconstr Surg* 9:46 1 360.

Extensive loss of the scalp has always been a difficult surgical problem. Step by step through surgical history the accepted methods of treatment used today have developed.

A brief but thorough review of the anatomy of the scalp is given. The anatomical features have a bearing on the results of trauma, on the treatment of the loss and at times, on the etiology of that loss.

Large losses of the scalp may be caused by (1) burns—thermal agents, chemical agents, electricity or radiation (2) impacts of sharp or blunt objects (3) infection (4) scalping—by paws of animals or by humans, (5) industrial accidents—entangling of hair in rapidly moving machinery.

A brief résumé of treatment through the ages is given, and the general care of patients is discussed.

Seven case reports are presented to illustrate the treatment of scalp loss in various circumstances.

Small defects may be closed by extensive undermining in the subaponeurotic area, with relaxing or cross-hatching incisions from below through the gales but not through the skin or superficial fascia.

In extensive losses of the scalp, every effort should be made to close the wound as soon as possible by skin grafting. If any hair bearing tissue remains, it can be utilized later as flaps to areas best suited for cosmetic purposes.

The pericosteum is vascular enough to take skin grafts. Periosteal flaps and tags should be sutured into position and grafts placed upon them. Split thickness grafts cut with the dermatome are most suitable. If the entire scalp cannot be covered at once, the anterior portion should have priority since it is here that the worst deformities (ectropions) occur.

In the second case reported, an attempt was made to reapply the completely detached scalp. Only about 8 per cent of the replaced scalp survived.

If periosteum has been lost, a vascular bed for grafting must be obtained. In the author's hands, chiseling away the outer cortex until multiple bleeding points showed themselves has been simplest and most satisfactory. In a week or slightly more granulations well able to sustain a split thickness graft are present.

Inadequate early treatment results in two common, late complications. Late contracture may result in severe ectropion of the upper eyelids. Excision of the scar and replacement with a dermatome graft is the treatment. The second late complication

is the breaking down of scar epithelium with occasional carcinomatous degeneration. After removal of the scar or malignancy, or both, it may be necessary to use a tubed pedicle flap for closure.

EARL H. KILPATRICK, M.D.

Wass, S. H.: The Odontomes and Other Affections of the Jaws: Their Pathology, Diagnosis and Treatment. *Gays Hosp Rep Lond* 1946, 95:1.

Among the odontomes (cysts, tumors, and malformations of the jaws arising from tooth germ) and the dental and dentigerous cysts, the adamantinoma or multilocular cysts are the more important ones, and are discussed as to pathology and clinical picture. Among other lesions, the osteoclastoma, osteofibroma, osteomyelitis, and actinomycosis are discussed and illustrated by roentgenographs and photographs of pathological specimens, and roentgenographs of lesions of differential diagnostic importance (carcinoma) are presented.

In his discussion of treatment, the author stresses the necessity of complete removal even of the benign, noninflammatory lesions (except fibro-osseous tumors in which cases complete removal is not essential) if recurrence is to be avoided.

The malignant lesions comprise the adamantinomas, epitheliomas of the alveolar process, metastatic carcinomas, and sarcomas. The author does not discuss the latter 2 lesions in detail. Epitheliomas respond mostly to irradiation. Adamantinomas are nonradiosensitive and require radical excision followed by bone grafting, which may be a formidable operation in the aged. Curettage may be deemed preferable in some of these cases although it is inevitably followed by recurrence.

Radical operation, likewise, is the author's choice for osteomyelitis of the jaw and neither bone drilling nor penicillin will prevent the spread of the disease. He states that even in late cases with much soft tissue swelling, delay is ill advised, and bold approach to the bone and radical and extensive excision is needed.

The author then elaborates on his experiences as to details of treatment. For malignancy of the upper jaw the classical excision of the maxilla is now passed and for cysts and benign tumors the intraoral approach is satisfactory. On the mandible however, most all of the more extensive lesions are better approached from the outside. Such an approach gives better exposure and dependent drainage and avoids severance of the mucosa. The author's discussion on the technique of approach should be read in the original.

Wa is impressed by the efficacy of orally administered penicillin in controlling intraoral flora and

postoperative infection when oral mucosa had been opened. Penicillin given systemically will not cure osteomyelitis of the jaws unless all diseased bone has been removed surgically. Penicillin can be used to good advantage preoperatively and postoperatively in cases of oral surgery.

An incision behind the ramus ascendens and below the ramus horizontalis of the mandible gives good cosmetic results if it heals by primary intention. There is danger of injury to a branch of the facial nerve and to the inferior dental nerve the one resulting in objective the other in subjective disturbances. Bone defects of the mandible usually reconstruct themselves rapidly and completely.

HEINRICH LAMM M.D.

EYE

Adler F. H. Physiological Factors in the Differential Diagnosis of Paralysis of the Superior Rectus and Superior Oblique Muscles. *Arch. Ophthalmol.*, 1946 36 661

The differential diagnosis between paralysis of the superior rectus and the superior oblique muscle of the eye is discussed. According to Bielschowsky most vertical anomalies are due to paralysis of the superior oblique muscle, but according to Duane they are due to paralysis of the superior rectus muscle. Adler attributes most primary or congenital vertical motor paralysis to paralysis of the superior oblique muscle.

The differential diagnosis between paralysis of the superior oblique muscle of one side and paralysis of the superior rectus muscle of the opposite side can be made by the position of the head. Head tilt the most characteristic sign of paralysis of the superior oblique muscle, is attributed to the fact that contraction of this muscle in the primary position results in 56 per cent of the movement being intorsion so that in cases of paralysis, extorsion results which is compensable only by tilting the head in a position which again brings the two vertical meridians into parallelism, that is, tilting of the head to the opposite shoulder.

In paralysis of the superior rectus muscle the tilting is only slight because the superior rectus in the primary position exerts only 25 per cent of its pull as intorsion.

In all cases, the head is tilted toward the side opposite the paralyzed eye, e.g. in right hypertropia (paralysis of either the right superior oblique or of the left superior rectus) the head is markedly tilted toward the left shoulder if the right superior oblique is paralyzed and is only slightly tilted toward the right shoulder if the left superior rectus is paralyzed. Moreover if the patient's head is tilted by the examiner to the shoulder of the same side as the paralyzed eye, this eye will make an upward movement if the superior oblique muscle is paralyzed and it either will not move at all or will move only slightly downward if the superior rectus muscle is paralyzed.

JOSHUA ZUCKERMAN M.D.

Lloyd, I. A Survey of the Results of Lacrimal Strictureotomy. *Brit. J. Ophthalmol.* 1947 31 51

The author analyzes the results and the causes of failure in 33 cases of lacrimal strictureotomy. The advantages of the French technique compared with those of other methods of treatment of lacrimal obstructions are discussed.

The French method consists of opening the lower canaliculus with a Weber knife for 3 mm. and dilating the canaliculus with a number 3 sound. The strictureotomy knife is then passed down into the sac and engaged to the neck of the duct. It is held vertically and the edge rotated forward through an angle of 45 degrees so that it faces forward in order to prevent cutting of the lower part of the canaliculus where it opens into the sac. Gum-elastic sounds from number 11 to 14 are passed into the duct and the largest one is left in place for 10 minutes. Dilation is done at intervals of from 4 to 6 weeks for a period of several months.

Symptomatic relief was obtained in 76 per cent and complete cure in 52 per cent of this series of 33 strictureotomies. The French claim cure in 100 per cent of the cases with no bony obstruction and in 70 per cent of those with such obstruction. Seven failures were attributed to various causes such as impassable stricture, very tight strictures, infection with mucopurulent regurgitation and burn scars.

The operation of strictureotomy can be performed in the outpatient clinic. Although the presence of a stricture at the junction of the lacrimal sac and the nasolacrimal duct has been denied roentgenologic findings and open operation have revealed that this abnormality exists in many cases of epiphora.

JOSHUA ZUCKERMAN M.D.

Stallard H. B. The Intraocular Foreign Body. A Series of 72 Cases in the B.L.A. *Brit. J. Ophthalmol.*, 1947 31 12

The author reports a series of 72 cases of retained intraocular foreign body. He discusses the methods of x-ray localization, and the various types of giant electromagnets used for removal of foreign bodies. Speed is important when daily convoys deliver several hundred wounded at a time. The average time for each case was 3 minutes for suturing a limbal ring into place, 10 minutes for the x-ray examination, and from 7 to 12 minutes for the extraction of the foreign body by the scleral route.

In most cases the scleral route was indicated for extraction of the foreign body. This route is simpler and less traumatizing than the anterior route. The danger of vitreous loss is negligible. No vitreous was lost in any of the cases in this series. Retinal detachment, generally considered a complication of the scleral route, does not occur if diathermy is used around the incision in the sclera.

Of this series of foreign bodies 69.3 per cent were extracted, 51.3 per cent by the scleral route and 18 per cent by the anterior route.

To extract war muskles of feebly magnetic alloys the terminal of a very powerful electromagnet must

be placed between the lips of the scleral incision and brought as close as possible to the foreign body

JOSUA ZUCKERMAN, M.D.

Mann I. Pirls, A., and Pullinger B. D.: *Lewisite Lesions of Rabbits Eyes. Am J Ophth* 1946, 29 135

In this article the authors contrast lewisite induced lesions with the results of mustard gas application. The work was carried out experimentally on rabbits' eyes. The effects of lewisite in contrast to those of mustard gas show that

1. The action is immediate and painful.
 2. There is an immediate strong miotic action
 3. Perforation and loss of an eye are caused with relatively small doses (0.001 cc.) perforation may occur within a few days without vascularization or later after the entry of blood vessels.
 4. Vascularization is independent of the site of the primary lesion. It occurs when a sufficient dose of the lewisite reaches either the cornea or the limbus.
 5. All lesions run a definite course to recovery or destruction not all vascular lesions perforate there are no relapses and no recurrent hemorrhages.
 6. Cholesterol and other lipid scars do not occur and there is no late breakdown due to them. The end result of a nonperforating severe lesion is a dense fibrous scarring with pigment proliferation on the corneal and conjunctival epithelium.
 7. Edema of the lids and conjunctiva is immediate and severe. Edema of the cornea is extreme with all but the smallest doses.
 8. Involvement of the iris and ciliary body is early and severe followed by gradual depigmentation and shrinkage of the iris stroma.
 9. The corneal vessels do not show the characteristic varicosities of vessels subjected to mustard gas. They are straight and evenly and radially arranged. No characteristic vessels appear in the conjunctiva.
- Twenty-seven rabbits were studied in this series and it was concluded that lewisite has a more destructive effect than mustard gas. A table is included to show lewisite lesions and their varying severity in the eyes studied.

HUNTER H. ROMADKE, M.D.

Thygeson P.: *Cytology of Conjunctival Exudates. Am J Ophth*, 1946 29 499.

The author's investigations were carried out in an attempt to evaluate the cytologic findings of conjunctival diseases. Over 2,000 examinations of conjunctival scrapings, exudates, and follicular excretions stained with Giemsa stain, Wright's stain, and the Hansel stain formed the basis of the article.

The most frequent cytologic reaction seen in acute and chronic conjunctivitis was a polymorphonuclear leukocyte reaction. A high polymorphonuclear reaction was found also in conjunctivitis associated with erythema multiforme, Reiter's disease and psoriasis arthropathica. However there was no leukocytic response in *Neisseria catarrhalis* and diplobacillary infection. It was concluded that the di-

agnostic significance of the polymorphonuclear exudate was of limited value.

The eosinophil was found to be the cell having the greatest diagnostic value since except for ocular pemphigus an eosinophilia proved to be an almost certain indicator of conjunctival allergy. It was invariably present in the conjunctivitis of hay fever the conjunctivitis due to drug and cosmetic allergy and vernal catarrh in the acute and usually in the quiescent stage. An eosinophilia is not a characteristic of bacterial allergies and therefore not found in pityriasis conjunctivitis.

Small numbers of basophils were not infrequently seen in nonallergic inflammations but large numbers were characteristic only of allergic inflammations and tended to parallel the conjunctival eosinophilia.

Mononuclear cells, and the lymphocytes in particular were consistently found in epidemic keratoconjunctivitis and acute follicular conjunctivitis (Beale). A pure reaction was also found in the acute herpetic conjunctivitis and the conjunctivitis secondary to molluscum contagiosum.

Plasma cells were rarely found except in trachoma. The epithelial cells were found to be keratinized and usually covered with xerosis bacilli in vitamin A deficiency. Keratinization also occurred as a result of exposure as in old ectropion, trachoma, or pemphigus. In keratoconjunctivitis sicca there was a keratinization of the epithelium and an increase in the number of goblet cells. No diagnostic changes were found in the epithelium of trachoma patients.

No diagnostic differentiation could be made between the expressions of the nontrachomatous follicles but there was a significant difference between them and the trachomatous follicles. The latter were characterized by the germinal center cell, believed to be a lymphoblast, lymphocytes, plasma cells, occasional monocytes, and large macrophages (Leber cells). The nontrachomatous follicular material contained small mononuclear cells, mostly lymphocytes, a few lymphoblasts, and small macrophages, but without the degenerative changes found in the trachomatous follicles.

The author believes that the cytologic examination of the conjunctiva is of diagnostic benefit in many cases of conjunctivitis.

ROGER H. JOHNSON, M.D.

Moncreiff W. F.: *Surgery of Congenital Cataract. Am J Ophth*, 1946, 29 1513

The author has presented his modification of the technique of needling congenital cataracts in patients between the ages of 1 year and 6 years. After well dilating the pupil the needle-knife is inserted through the limbus of its temporalmost portion, and a vertical incision is made in the lens capsule and into the anterior cortex. Multiple incisions in the superior capsule and cortex are then made the nucleus is cut into several fragments and a few light strokes are taken in the posterior cortex without injuring the posterior capsule. If too much aqueous is lost before completing these maneuvers it is restored with an

irrigate before continuing with a larger needle-knife. When the lens is thoroughly stirred up, the knife is removed and some aqueous is allowed to escape. The lens remnants are then irrigated with an anterior chamber irrigator through the needle knife opening.

The author reports 6 such needlings in which he obtained clear openings with the first needling and without complications.

In discussion the author states that he believes the needling should be done as soon as the pupil can be well dilated and that both eyes should be cared for at once unless there is a definite contraindication. He believes that too much traction on the zonule and ciliary body can cause secondary glaucoma and iridocyclitis. His method of breaking up the lens into small pieces and irrigating them into the anterior chamber is designed to prevent glaucoma by leaving the lens remnants in front of the iris where they cannot exert traction or the Ziegler operation should be used in this age group—the former because of the danger of iris prolapse and the latter because of damage to the vitreous.

ROBERT H. JOHNSON, M.D.

Feigenbaum, A., and Kornbluth, W. Posterior Ring Abscess of Metastatic Origin in Behcet's Disease. *Bru J Ophth.* 1946 30 729

The authors discuss posterior ring abscess of metastatic origin in association with Behcet's disease. The syndrome which represents a chronic septic condition produced by the staphylococcus aureus generally occurs in patients with tuberculous or syphilitic. The following signs are usually present: aphthous stomatitis, ulcers, uveitis (recurrent and a skin condition resembling erythema nodosum).

In metastatic cases the infective agent is brought to the eye by the vascular route in traumatic cases it is introduced into the interior of the eye through the perforating wound. In either case the action of the organisms intraocularly is probably the same. Forty-two cases are reported in the literature—18 of metastatic origin and 24 of traumatic origin.

A case of metastatic nontraumatic posterior ring abscess of the cornea in a male patient 28 years of age is presented. The authors believe that in combination with other etiologic factors increased intraocular pressure is a factor in the production of a posterior ring abscess.

Hirschfeld, H., Jacobson, M., and Jettlinek, A. New Treatment for Hearing Disorders. *Arch Otol Rhinol* 1944 44 686

The writers describe a new treatment for hearing disorders using a combination of amino acid and vitamins. Quick and lasting results seem to occur. A brief comment on the pharmacology of the

The medication was given in two ways. In the first 2 c.c. ampoules containing thiamine riboflavin pyridoxine nicotinamide choline glutamic acid histidine methionine and urea were used. The reasons for using these particular drugs were explained. In the second form of treatment the medication was given in capsule form and thus a wider variety of amino acids could be used. Vitamin A thiamine riboflavin pyridoxine ascorbic acid nicotinamide calcium pantothenate cysteine urea tyrosine choline glutamic acid liver concentrate and dried yeast were in each capsule. The amount of each drug used was not given.

During the first 2 weeks of treatment the patient received 2 c.c. intramuscularly 3 times a week and twice a week thereafter for 12 injections but more resistant cases may receive a second series of treatment after a pause of 2 weeks. This was supplemented by the daily oral administration of 3 capsules.

The clinical investigations were carried out in the Hard of Hearing Clinic of the New York Polytechnic Medical School and Hospital. Fifty-three patients were examined and treated there and 36 additional patients were treated privately. Thirty of those treated at the hospital showed great improvement 13 some improvement and 10 no improvement. 4 failed in the continuous treatment.

The full effect of treatment was usually reached within 2 to 4 weeks. Further treatment did not seem to give any additional advantages. Some patients kept the original gains but in older patients it is advisable to continue treatment with the capsules. Increase in acoustic perception with the capsules speech range but the best gain occurred in the high tones. Some patients showed improvement in one ear only which was usually the one that had the shortest duration of the deafness. A case of bilateral binocular dyspharmonia was also treated and the phenomenon disappeared nearly completely. The writers state that this medication may be of value in preventing acoustic disorders that occur after exposure to loud noises.

Included are data on the patients treated including audiograms on different patients made before and after treatment.

WILLIAM A. MARRAS, M.D.

Krauss, F. H. Penicillin Therapy in Otorhinolaryngologic Practice. *Arch Otol Rhinol* 1946 44: 647

The authors carried out a study on the effect of penicillin in ear, nose and throat diseases. They recognize the fact that poor results may be obtained in cases when it is not possible to get the drug in direct contact with the infection.

A total of 113 cases were studied including cases of acute and chronic sinusitis of otitis media and of the middle ear. They have been grouped according to the method of treatment as well as on the basis of the nature of the procedure. The procedure was as follows: 1. Intramuscular penicillin was administered in a strength of 1,000 unit to the culic in a strength in one series

of cases Proetz's displacement therapy was employed. In another series the solution was instilled directly into the maxillary sinuses. In the less severe infections the topical administration of penicillin by nose drops alone was the procedure followed. In infection of the middle ear the penicillin was introduced directly into the middle ear by pressure and finally the topical administration of the drug was fortified by parenteral administration 10,000 units being given every 3 hours by intramuscular injection for from 2 to 5 days. This method was employed particularly in cases of associated mastoiditis and chronic sinus infections.

Forty seven cases were treated by Proetz's displacement therapy, all with excellent results. Treatment was given daily and each patient instructed to use 10 drops of the penicillin solution in each nostril every 3 hours during treatment.

About 25 per cent of the patients with acute or chronic sinus infection were treated only by use of penicillin nose drops. The results in this group were inconsistent and not entirely satisfactory.

Four children treated by the Proetz technique had good results.

Ten cases of antral infection were treated by the instillation of the penicillin solution into the maxillary sinuses. Six cases cleared up after the second irrigation and in 2 cases in which permanent windows were present the infection was controlled with penicillin put into the sinuses every 3 hours for 3 days. Some failures occurred even though similar cases gave excellent results.

The patients with chronic otitis who were treated usually had concomitant sinusitis. The latter reacted well to the penicillin medication but the chronic otitis showed no definite improvement that could be attributed to the local use of penicillin. A special clinic was set up and all chronic ear cases were referred there. These were treated by forcing the penicillin solution into the middle ear with a pneumatic otoscope.

Acute titis media responded very well to the intramuscular injection of penicillin when the disease was due to penicillin susceptible organisms. When penicillin injected intramuscularly was used along with mastoidectomy in cases of acute mastoiditis, the results were excellent as shown by the middle ear and the wound became dry in an average of 3 days instead of the normal 7 to 10 days or longer.

The article includes several reports of successful and unsuccessful cases. Several tables are also included which show the results of the penicillin treatment in the different groups of cases.

WILLIAM A. AERODON, M.D.

Day, E. M.: Appraisal of Fenestration Operations: Report of 160 Cases. *Arch Otolaryngol.*, 94:6 44-547

The fenestration operation is undoubtedly the greatest otological contribution of the present generation. The trend seems to be towards success in a higher percentage of cases but attempts to analyze

reasons for success or failure are needed in the hope of further improvements.

If practical hearing of normal speech can be achieved by the operation, the author believes it to be far superior to the distorted hearing obtained with a hearing apparatus. If the improvement is insufficient for the understanding of normal speech, the operation is considered a failure regardless of the amount of improvement since some form of hearing aid is still needed. Speech tests are a better indication of the ability to hear than the threshold level for pure tones. Some patients have practical hearing with a threshold level of 30 to 35 decibels others require closer to a 55 decibel threshold.

The diagnosis of otosclerosis should present little difficulty. Ninety-four of 100 consecutive cases showed fixation of the stapes on testing with a probe at operation. Gelle's test is thought to be useful. The family history was positive in less than one-half of the cases, and some pink discoloration of the medial wall of the middle ear was seen in 30 per cent.

The operation is of greatest value in young adults, and of less and less value after the fourth decade.

Hearing loss by air conduction must be below the practical level for speech bone conduction loss should be slight especially at 2,000 cycles. Bone conduction audiograms are likely to be inaccurate. Patients who are psychologically unstable are accepted with hesitancy. A clean upper respiratory tract and freedom from nasal allergy are important. A rapid loss of hearing with diffuse discoloration of the inner wall of the inner ear indicating extensive involvement makes the prognosis more questionable. The operation has no effect on the otosclerotic process.

Irrigation of the wound with saline during operation is found to be a help whether constant or intermittent.

Three minor changes from the standard technique of the Lempert nov-ovis operation have been found helpful. The wedge of skin and tissue between the tragus and helix is not removed but a single incision is employed at that area. A partial mastoidectomy is preferred to a complete exenteration, to produce more rapid healing and reduce the size of the resulting air chamber closer to the original. Melted paraffin has been discarded and small pedgets of paraffin gauze have been substituted to hold the flap. Packs are removed on the fifth day.

Care is directed to the method of preparing the flap and removing tiny scales of bone which have adhered to the periosteal surface.

Results in the first 100 cases are given.

Some improvement followed the adoption of the nov-ovis operation. In the last 50 consecutive cases out of 90 in which this technique was used, 46 patients have practical hearing, 1 patient has unsatisfactory hearing, 1 patient is unimproved, and in 2 patients hearing is worse. The fenestra closed in 1 of the last 50 cases.

There have been no serious complications, no facial weakness, operative infections, nor dead baby

nths in the author's series of 100 cases. Postoperative infections in the cavity have been frequent after the first few weeks, but were superficial and did not affect the results. In 2 patients acute secretory conditions of the middle ears developed some months after operation. In one of these the hearing showed a permanent loss of 10 to 15 decibels, but in the other patient hearing was recovered to the previous postoperative level. Four patients had an attack of suppurative otitis media at some later time but all recovered without damage to their hearing.

In 7 cases of pregnancy following operation no appreciable loss of hearing in either ear was found to occur.

MOUTH

Brown J. B., Peterson LeR., Cannon B. and Moore A. M.: Facial Asymmetry and Malocclusion from Hyperplasia of the Mandible (Correction by Operation) *Plast Reconstr Surg* 1946 1 284.

The authors report 1 case of facial asymmetry and malocclusion from hyperplasia of the mandible and state that the condition occurs only rarely.

Progressive enlargement of the left side of the jaw with malocclusion was noted over a period of 5 years in a 27 year old female. The asymmetry was due to an increase in length of the ascending ramus and also to thickening of the body of the left jaw. The entire left side was out of occlusion the discrepancy being 6 mm. in the bicuspid and first molar area. No associated systemic disease was present.

The condyle and its elongated neck were removed through an external incision curved down from the temple close to the crux of the helix and over the tragus.

Elastic traction was attached to previously placed multiple loop wiring and maintained for 4 weeks.

The teeth were brought into occlusion and the deformity was removed. Mastication has been satisfactory.

On microscopic examination the bony substance was found to be normal. JOHN R. LINDSAY M.D.

McNichol J. W. and Roger A. T.: An Original Method of Correction of Hyperplastic Asymmetry of the Mandible *Plast Reconstr Surg*, 1946 1 288.

The authors describe an original method for correction of this rare deformity.

Plaster models of the dental arches are made and the existing occlusion recorded. The lower model is cut in reduced in size if necessary by removal of teeth and repositioned so as to correct the facial deformity and produce functional occlusion. The sections of the lower model are united. It now indicates which teeth should be extracted and the best location for sectioning the mandible. The method of fixation of the mandibular fragments is decided. Sectional cast cap splints of German silver cemented to the teeth are usually best. Removable locks are prefab-

ricated by making a plaster model of the lower arch with the splints on the teeth and cutting and adjusting it with reference to the predetermined bite.

The first stage of operation consists in bilateral complete section of the mandible at predetermined points the removal of full thickness section on the long side together with associated teeth and the removal of excess bone along the inferior margin of the mandible on the long side.

Although the mandibular nerves are sacrificed the chances for continued function of the teeth are good.

The second stage of operation consists in the application of bilateral cancellous bone grafts to points of previous bilateral section 3 to 4 weeks after the first stage.

The third stage of operation is undertaken in from 5 to 6 weeks after the second procedure at which time filling out of the concave side of the face by a soft tissue fat fascial dermal graft is accomplished.

The method described is believed to provide better functional occlusion and correction of facial deformity than simple resection of the head of the condylod process on the affected side.

One case successfully treated by this method is described in detail.

JOHN R. LINDSAY M.D.

Brown, J. B. Peterson LeR., Cannon B. and Lischer C.: Ankylosis of the Coronoid Process of the Mandible (and Associated Scar Limitation of Jaw Function) *Plast Reconstr Surg* 1946 1 277.

In gunshot and shell fragment wounds about the coronoid process fibrous tissue formation or comminution of bone with fixation or both, may produce ankylosis of the mandible and loss of mouth function.

An ankylosing process of the temporomandibular joint may extend to involve the coronoid process. An ankylosis starting in the region of the coronoid process may tend to extend to the joint but early treatment may prevent involvement of the articulation.

Treatment varies according to the extent of fixation. It includes active exercises with the use of a rubber block forcible dilatation and blocking the mouth open section of fibrous tissue and blocking removal of the coronoid process with or without blocking and resection of the jaw below the ankylosis to create a false joint.

While the extent of the ankylosing process may not be evident on examination, the coronoid should be approached first if injury points in that direction.

Of 27 patients with limited mouth opening 8 had bony ankylosis involving the coronoid 3 had severe soft tissue cicatricial involvement, 5 had a strong fibrous attachment between coronoid and zygomatic processes, 4 had trismus due to a foreign body in kinetic muscular areas. In 10 the trouble was due to scarring of muscle and surrounding tissues.

Foreign bodies causing trismus should be removed. Surgical treatment for bony ankylosis involving the region of the coronoid process consists of removal

of the process from inside of the mouth and enough of the surrounding displaced bone to prevent reunion. The crux of the operation for ankylosis of the temporomandibular joint is removal of a wide enough area of bone and scar to prevent reunion. Fascial transplant is thereby made unnecessary.

Enastracheal ether or cranial block anesthesia is used. The intraoral incision extends along the anterior border of the coronoid and the ramus is exposed by blunt dissection. The ankylosis is chiselled free. Usually the entire coronoid process is removed to create a large defect and prevent reunion. Treatment is the same for bony or extensive fibrous tissue fixation. Bleeding may be controlled by packing. Postoperative jaw exercises with the use of a rubber block are important adjuncts to treatment.

JOHN R. LEROY, M.D.

Thoma, K. H., and Goldman, H. M.: Odontogenic Tumors. *Int. J. Orthodont.*, 1946 3: 763.

The authors review 75 cases of odontogenic tumors for the purpose of (1) formulating a proper classification, (2) describing their structure and (3) illustrating the inductive effects of one tissue on another in the production of mixed tumors.

The following classification is adopted:

I. Epithelial tumors (36 cases studied)

1. Adamantoblastoma

2. Enameloma

II. Mesenchymal tumors (15 cases studied)

1. Odontogenic fibroma

2. Dentinoma

3. Cementoma

III. Odontogenic mixed tumors—odontomas (24 cases studied)

1. Soft odontoma—epithelium and mesoderm

2. Soft and calcified odontoma—adamantoblastoma arising in conjunction with a forming or completely formed odontoma; all sorts of histological variations due to the inductive effects of one tissue on another

1. Completely formed odontoma with enamel dentine pulp cementum periodontal membrane

(a) Compound (many small teeth)

(b) Complex (irregular tooth structure)

As may be seen, the odontogenic tumors are either of epithelial or of mesenchymal origin and are either soft or calcified. The soft epithelial tumor is called adamantoblastoma; the calcified, enameloma. Like the soft mesenchymal tumor is called fibroma; the calcified if dentine is produced, is called dentinoma; and if cementum is produced, is called cementoma. The authors state that the mixed tumors are designated as odontomas and they may be (1) completely soft and (2) completely calcified.

The authors state that the adamantoblastoma is the most common odontogenic tumor and they are being clinically and degenerately

rence after operation is due to incomplete removal. The enameloma, also called enamel pearl, occurs at the bifurcation of the roots of molars and premolars, and between the roots or at the cervical margin of single rooted teeth. The odontogenic fibroma originates from the embryonic tissue of the dental papilla or follicle and, later from the periodontal membrane. It may occur in the coronal or apical region of the tooth. If calcification occurs, it leads either to dentinoma, located in the coronal region, or to cementoma, located in the apical region, although the pure forms of both are very rare. The mixed tumors contain a variety of elements such as enamel dentin cementum pulp and periodontal tissue. In the soft types the stroma predominates, sometimes becoming fibromyxomatous. The epithelium may form a very minor component. In the soft and calcified types of tumor all possible phases of dental production are encountered. Calcification of the epithelial cells leads to the so-called ghost cells. Intermingled cystic areas are common. The completely formed odontomas may be compound, containing numerous rudimentary teeth, and complex when the calcified structures show no resemblance to dental tissue. Both types are usually encompassed by a cyst membrane.

The inductive effects of one tissue upon another are well demonstrated in the mixed odontogenic tumors. The epithelium in these tumors seems to stimulate dentine formation. However dentine production may also be initiated by fibroblastic activity in the absence of epithelial cells. Neoplastic adamantine tissue and enamel forming ameloblasts account in part for the formation of the soft and calcified odontogenic mixed tumors. T. LEROY, M.D.

NECK

Salter, W. T.: The Circulating Thyroid Hormone in Blood and Lymph. *West. J. Surg.* 1947 55: 5.

It appears that circulating thyroid hormone is intimately connected with protein and with protein that can leak through capillary walls. The preliminary formation of this protein carrier perhaps explains the characteristic lack in the response to thyroid medication. The accumulating measurements of protein-bound iodine in the serum indicate that it is our best gauge of net thyroid function. The measurements in lymph and in tissues are only preliminary.

ROBERT J. BARNETT, JR., M.D.

Astwood, E. B., and Vanderlass, W. P.: Treatment of Hyperthyroidism with Propylthiouracil. *Ann. Int. M.* 1946 25: 813.

The authors report their observations in 100 cases of hyperthyroidism in which treatment with propylthiouracil was carried out over a period of 100 days. The requirements varied from 50 to 100 mg. per day. The more severe cases, so the optimal dose for restoration. In the milder cases usually adequate. The

larger doses were given until the disease was believed to be under control, after which the smaller maintenance doses were employed. There were no significant evidences of poisoning with the doses used.

CLINTON H. THOMES, M.D.

Rawson R. W., and McArthur J. W. What Has Thiouracil Taught Us about the Pathologic Physiology of Graves Disease? *West J Surg.*, 1947 55 27

Studies were made on 7 patients suffering from Graves disease. The histology of the thyroid gland was studied from biopsy specimens taken before any therapy after the administration of thiouracil, and also after the administration of thiouracil and iodine.

The mean acinar cell height before treatment with thiouracil was 13 μ micra. After thiouracil treatment the average was 13.9 μ micra. After thiouracil treatment plus iodine the average was 7.2 μ micra.

The excretion of tracer doses of radioactive iodine in the urine was determined in 3 cases before beginning any treatment, and in 6 cases after thiouracil had caused a fall in the rate of metabolism to a standard level. The average excretion before treatment with thiouracil was 25 per cent of the administered dose. In the same 3 cases it had risen to 83.7 per cent after thiouracil treatment. In 6 cases the average radioiodine excretion was 80.3 per cent after thiouracil treatment.

The iodine values of thyroids removed at operation showed a total iodine average of 23.1 μ g thyroglobulin value of 7.0 mgm. and anodially stable iodine average of 8.3 mgm. These values are comparable to the values attained from the thyroids of thyrotoxic patients upon whom thyroidectomy was performed after treatment with thiouracil only.

These findings suggest that the thyroid gland of Graves disease becomes more hyperplastic under thiouracil treatment that thiouracil prevents the utilization of iodine by the thyroid, and that notwithstanding this block to the collection of iodine produced by thiouracil, iodine causes involution of the thyroid gland in Graves' disease.

RICHARD J. BENNETT JR., M.D.

Wright, L. E. A. The Estimation of 2 Thiouracil in Plasma and Urine following Its Administration in Thyrotoxicosis. *Med J Australia*, 1946 2 800.

The author discusses the preparations of reagents, the colorimetric estimation, the estimation of the drug in urine, the preparation of standard curves for oxalated or citrated plasma, the use of whole blood, the effect of altering the hydrogen ion concentration, the estimation of thiouracil in oxalated pooled mouse plasma, the distribution of 2 thiouracil between the red cells and plasma, the effect of other substances on the estimations, and the collection of urine and plasma.

The excretion of 2 thiouracil in the urine of 24 thyrotoxic patients who received different dosages is discussed. It was found that the action of 2 thiouracil

in thyrotoxicosis is "quantitative" in nature. The requirements of the patient at a particular time can be found by estimating the excretion of the drug on normal fluid intake, and then the excretion of the drug on increased fluid intake. It is recommended that a fluid intake which is larger than usual be taken because of the smaller solubility of the drug in the urine in comparison with its solubility in the plasma.

RICHARD J. BENNETT JR., M.D.

Watson E. M. The Treatment of Toxic Thyroid Disease with Thiouracil. *Edinburgh M J* 1946 53 609

This report is based on a series of 60 hyperthyroid patients treated with thiouracil. The dose of thiouracil used initially for adults was from 400 to 600 mgm. daily. The development of severe toxic reactions is most likely to occur during the first 3 weeks. The time under thiouracil therapy necessary to effect a satisfactory response depends upon (1) the nature of the disease (toxic adenomas respond more slowly than 'primary' hyperthyroidism) (2) the severity of the thyrotoxicosis (3) the duration of the hyperthyroidism (4) the size of the goiter and (5) the previous treatment with iodine.

After from 6 to 9 months of successful therapy with thiouracil it is often possible to stop the drug with a continuation of the remission. This was accomplished in 20 of the author's 60 patients all 20 of whom are still under observation. There is no condition of thiouracil escape or resistance comparable to iodine escape or resistance. However a small percentage of patients, probably around 5 per cent, are refractory to thiouracil for some reason unknown at present. There were 5 such cases in this series of 60.

The author does not believe that thiouracil has supplanted the surgical treatment of goiter except in certain selected cases. He believes that most, if not all, toxic nodular goiters should be treated surgically not only because of the variability of their response to thiouracil but also because of the danger of malignancy. Lugol's solution is administered both preoperatively and postoperatively and thiouracil is discontinued for a week prior to operation.

The blood iodine levels were determined in 43 of the patients. The administration of thiouracil brought a decline of the blood iodine in 32 of the 43 cases in which determinations were made. Similarly in 36 of the 46 cases in which blood cholesterol determinations were made a rise occurred following thiouracil therapy.

The use of thiouracil during pregnancy is a question deserving of careful consideration. Experimentally it has been shown that hyperplasia of the thyroid gland and retarded development were presented by the offspring of mothers receiving thiouracil. Similar reports of thyroid hyperplasia in newborn infants of mothers treated with thiouracil have been recorded. The author believes that if the drug is given with caution thiouracil may be used during pregnancy. He advises that in such cases the basal

metabolic rate be maintained near the upper range of the normal. A high concentration of thiouracil is present in the milk of such mothers, and they should not be permitted to breastfeed their infants.

The author reports that 1 in 200 thiouracil treated patients succumbs to the toxic reaction of the drug. Agranulocytosis, simple leucopenia, drug fever, cutaneous reactions as well as gastrointestinal upsets, jaundice, lymphadenopathy, swelling of the salivary glands, myalgia and arthralgia have been reported as complications of the use of this drug. While individual hypersensitivity is of the greatest significance in the determination of the toxic reaction, excessive dosage and intermittent courses of administration seem definitely to increase the number of toxic reactions.

Newer thiouracil derivatives, propyl thiouracil and ethylthiouracil, appear most promising. Apparently thiouracil acts by interfering with the formation of thyroxine by preventing the utilization of iodine. The use of thiouracil in cases of angina pectoris is briefly commented upon.

F. J. LITTMER, M.D.

Dobyns, B. M.: Exophthalmos and Tissue Changes in the Guinea Pig following Administration of the Thyroid Stimulating Hormone of the Pituitary Gland. *Ann. J. Surg.* 1946 34 4.

Following the injection of thyroid stimulating hormone conspicuous exophthalmos occurs in guinea pigs regardless of the presence or absence of the thyroid gland or the testes. Concurrently a generalized connective tissue reaction occurs throughout the body and a profound change occurs in the body fat. Fat deposits are rapidly depleted and replaced by edema and connective tissue. Polymorphonuclear leucocytes and macrophages participate in this reaction and appear to phagocytize fat. Macrophages appear to become fibroblasts which lay down connective tissue.

As further evidence of profound changes in fat following the injection of thyroid stimulating hormone great quantities of lipid appear in the liver, kidneys, muscles, and in some epithelial and reticuloendothelial cells. Values for plasma lipoids are elevated and the polymorphonuclear cells of the blood stream have been found to contain increased quantities of fat.

The data suggest that as a result of the administration of thyroid stimulating hormone quantities sufficient to produce exophthalmos there is a generalized alteration in the metabolism of fat throughout the body and a connective tissue reaction is associated with it. Thus, many of the changes in the orbital

tissue which produce exophthalmos are expressions of generalized tissue changes.

Troell, A.: Malignant Goiter. *Acta chir. scand.* 1945 94 533.

In a series of 4,500 patients submitting to surgery of the thyroid gland, the author reports findings of malignancy in 42. In 18 of these, the condition was considered benign prior to operation.

Radical resection was carried out in some of the cases, and in others less extensive resection was done. Since the postoperative course was about the same in both groups, the author believes that usually a less radical operation should be performed.

The prognosis in cases of adenomatous goiters in patients over 50 years of age with a short anamnesis, change in voice, shortness of breath, and a high sedimentation rate is believed to be unfavorable. Diagnosis is difficult and no rigid rules of treatment can be formulated. However x ray therapy following surgery or in inoperable cases, is believed to be important.

CLINTON H. THURMAN, M.D.

Clerf, L. H.: Sarcoma of the Larynx; Report of 3 Cases. *Arch. Otolaryng. Chic.*, 1946 44 517.

The author states that sarcoma is a disease of adult life and that it occurs more commonly in men. Of the 3 cases of sarcoma of the larynx on which the present report is based all were men. Six of the patients were from 49 to 59 years of age, one was 23 and one 75. One had had a similar lesion 21 years previously.

The commonest lesion is fibrosarcoma. The tumor is single, often pedunculated, nodular, firm, usually not ulcerated, and relatively avascular. In the series were also 1 case each of fibro-osteosarcoma, chondrosarcoma, lymphosarcoma, and extramedullary plasmacytoma.

Diagnosis is difficult and can usually be made only by biopsy.

The patients in this group were treated as follows: In the case of chondrosarcoma and the case of fibro-osteosarcoma, laryngectomy was performed.

The case of lymphosarcoma was treated by irradiation. Three of the tumors were removed by thyrotomy; 1 was removed by a snare removing part of the arytenoid, and 1 by removing a segment of the vocal cord with cupped and tissue forceps.

Of 6 patients observed for 5 or more years post-operatively, only 1 patient died of metastases; 3 patients died of unrelated illnesses. Two patients are living and free from recurrence.

Two of the 8 cases have been observed for a period of but 3 months.

CLINTON H. THURMAN, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Gerlins, P. C.: Pacchionic Granulations and Brain Hernias. *J. Lar. Otol. Lond.*, 1946 61 261

Pacchionic granulations are described by the author to consist of arachnoidal flocks separated by a thin endothelial dura layer and connected with an intradural blood sinus. These granulations have a special function to perform i.e. to influence the brain pressure.

Brain hernias described as bulbous protrusions of brain tissue in the dura mater always developed in pacchionic granulations. The author states that such brain hernias are almost exclusively found at the base of the skull at the same sites of the pacchionic granulations.

The pathological importance of such brain hernias consists in the fact that they can conduct an otogenic infection especially when the infection proceeds through the tegmen tympani or pyramidal apex.

During a mastoid operation when the dura in the neighborhood of the tegmen tympani and in front of it is freed a pacchionic granulation or brain hernia may tear off. Through the dural fistula thus occurring an inflammatory process could quickly give rise to a leptomeningitis. These pathways are considered to be a factor in the intracranial spread of such extradural infections as may arise in the mastoid area.

HOWARD A. BROWN M.D.

Bennett, W. A.: Primary Intracranial Neoplasms in Military Age Group—World War II. *Mil. Surgeon*, 1946 99 594.

The author's material is derived from a comprehensive study of 446 intracranial tumors at the Army Institute of Pathology. These tumors were removed from World War II Army personnel of the age group from 18 to 38 years, inclusive. Accurate correlation with other series of cases is not possible because of the limited age group. Only primary intracranial tumors are included and the general divisions of this series are based on the morphological classification as well as the pathogenesis.

The Cushing classification is followed and the tumors are listed under their appropriate headings. A most complete pathological description of each type of tumor is presented with its general characteristics and special peculiarities. The article is interspersed with 106 illustrations of both microscopic sections and gross specimens. The clinical side is described by noting the symptoms, their duration, the order of their prevalence and the clinical diagnosis. Under each tumor heading there is an enumeration of the minor procedures that were performed such as spinal puncture, pneumoencephalography and ventriculography. In addition the number of craniotomies is tabulated and the

mortality rate carefully evaluated. As far as information is available, an attempt is made to list the number of cases which were given x ray therapy and those cases in which there was an associated history of trauma.

Of the 466 tumors studied, 281 (60.3%) were gliomas and of this group only 3 (0.7%) are listed as unclassified. Glioblastoma multiforme was diagnosed in 103 cases (22.1%) and astrocytoma in 63 cases (14.1%). The authors call attention to the fact that this ratio was reversed in other series based on different age groups. The incidence noted here of medulloblastoma 45 cases (10.1%) and pinealoma, 13 cases (2.9%), was considerably higher than in other series. Fifteen cases (3.4%) of neurofibroma and 39 cases (8.4%) of meningioma are reported a lower incidence than in other studies. This suggests that these types of tumors are more apt to be noted in older age groups. In this series only 16 cases (3.5%) of pituitary adenoma are tabulated. The remaining tumors were sparsely distributed among the rarer types of neoplasms. In the miscellaneous group there were 2 cases (0.4%) which were regarded as unclassifiable.

A few general conclusions are drawn. There is no great variation in racial incidence. The immaturity as well as the location of the lesion is of importance in determining the development and duration of the symptoms. The mortality rate is greater in gliomas than in other major types of tumors. It is directly related to the size, location and type of tumor. The author emphasizes the fact that in this study 10 per cent of all the deaths occurred after spinal puncture, encephalography or ventriculography or before any operative procedure was performed.

RICHARD C. SCHWEDER, M.D.

McKenzie K. G. and Proctor L. D. Bilateral Frontal Lobe Leucotomy. *Canad. M. Ass. J.* 1946 55 433.

Frontal lobotomy or frontal lobe leucotomy as the authors prefer to call it, has been the subject of a fairly voluminous literature in the United States for almost 10 years. The authors present a short history of the procedure and its rationale followed by a discussion of the results obtained in 27 cases. The technique, as described, severs approximately three fifths of the various association pathways between the frontal cortex and the thalamus and hypothalamus. These tracts run in the inferior portion of the white matter of the frontal lobes.

The operation is performed with a special instrument called a leucotome which is inserted into the frontal lobe through carefully localized burr holes $\frac{3}{4}$ inch and $1\frac{1}{4}$ inches respectively from the sagittal plane, with removal of the intervening portion of bone. The instrument is a sort of wire snare which can be opened or closed with the snare open the in

strument is rotated thus severing the white matter.

Special care is necessary in evaluating the patient from the cardiologist's point of view. Although cerebral hemorrhage is said to be the most serious post-operative complication no instance of this occurred in the present series of cases. Mild hypersexuality followed operation in about 25 per cent of cases (3 females 4 males) the intellectual impairment was slight failure of orientation and memory, persisting from several weeks to several months following the operation.

In the selection of cases for leucotomy all other standard methods of treatment had been tried and in all cases there was an underlying factor of fear agitation, and impulsive behavior. A heavy battery of psychometric tests was employed in evaluating the patient after operation as before operation the patient was inaccessible. The results varied with the type of mental disorder that was evident before operation. In the affective disorders 86 per cent of the patients were improved or cured and 61 per cent were able to carry on life outside a mental hospital. In the schizophrenic group 58 per cent were improved so far as nursing problems were concerned, and 25 per cent were discharged from the institution.

It was calculated that in this small series of 27 cases approximately \$70,000.00 were saved in hospital care. The article is supported by suitable summary tables and instructive diagrams.

WILSON VAN BUREGHEM, M.D.

Cawthorne, T.: Peripheral Facial Paralysis. Some Aspects of Its Pathology. *Laryngoscope* 94:6 56 653.

In reviewing Kettel's series (1943) of 93 cases of facial paralysis in which the nerve was operatively exposed the author shows that 31 of the patients suffered operative injury to the facial nerve in the fallopian canal proximal to where the chorda tympani leaves the nerve trunk. In 1 patient the nerve had been cut during operation at its exit from the stylomastoid foramen. Bell's palsy accounted for paralysis in 26 patients. In all of these patients there had been no response to faradic stimulation after 3 weeks, and in all but 4 patients taste on the anterior two-thirds of the tongue on the affected side had disappeared.

The author does not believe that failure of lacrimation on the affected side is a reliable test for a lesion of the nerve proximal to the geniculate ganglion. In many of these patients the nerve was found to be swollen and bulging above a positive constriction ring just above the stylomastoid foramen. At the site of the constriction many fine hemorrhagic streaks within the nerve were to be seen.

Chronic suppurative otitis media accounted for the paralysis in 15 patients; war injuries produced the lesion in 12 patients; basilar fracture extending into the petrous bone with severe damage to the nerve was present in 4 patients; neurofibroma of the facial nerve in 2 patients and of the acoustic nerve

in 1 patient was surgically verified and unusual accidents to the ear caused the paralysis in the remaining 2 patients.

Cawthorne has found in agreement with Bunnell, Ballance and Ducl and other modern otologists, that surgical exploration of the facial nerve is feasible and more useful than has commonly been believed.

JOHN MARTIN, M.D.

Lathrop, F. D.: Facial Nerve Surgery in the European Theater of Operations. *Laryngoscope* 56 665.

The author points out that though Ney in 1922, Bunnell in 1930 and Ballance and Ducl in 1931, demonstrated the feasibility of grafting the facial nerve in patients who had suffered traumatic paralysis of the nerve the methods used for the care of such casualties in World War II were as haphazard as they were in the first world war. The various mechanisms of the military type of injuries, together with the resultant defects, are discussed at some length. This author believes that testing for the presence or absence of increased lacrimation on nasal irritation is of value in determining whether or not the injury sustained by the nerve is located distal or proximal to the geniculate ganglion.

The commoner methods used to treat traumatic facial paralysis are decompression of the nerve within its bony canal end-to-end suture (not always possible even in a fresh wound) nerve grafting, hypoglossal facial anastomosis, and fascia lata slings for the sagging muscles.

In the author's group of 45 patients, the nerve was decompressed in 10 sutured in 12 grafted in 13 patients and anastomosed with the hypoglossal nerve in 1 patient. In the remaining 7 patients it was impossible to obtain a pathway for neurotization of the facial musculature.

Any procedure which actually puts the nerve ends in approximation such as end-to-end suture or grafting is definitely to be preferred to any anastomotic or plastic surgical procedure. The author is a strong advocate of the rerouting method of Bunnell, which may allow end-to-end suture to bridge gaps up to 25 mm. long if the nerve is properly removed from its canal and moved forward of its old bed in the facial canal.

JOHN MARTIN, M.D.

SPINAL CORD AND ITS COVERINGS

Kennedy, R. H.: The New Viewpoint toward Spinal Cord Injuries. *J. Surg.* 1946 2:4 57.

The appearance of the present article is particularly gratifying in that it indicates a new enthusiasm for improved care of the patient with an injured spinal cord. The author is sufficiently a realist to know that injury to the cord is damage done and that the essential cord lesion is not reversible, yet he along with others now active in the care of the military paraplegic, is sufficiently optimistic to believe that with proper early and rehabilitative care these patients can be returned to effective worthwhile living.

In contrast to the high mortality among patients with injured cords in the first world war it is pointed out that except for those who died early of massive injuries most of these patients have survived as a result of the greatly improved means of evacuation in the theater of war, with better early surgical care and with more intelligent care after reaching this country. He advocates the use of tidal drainage for the care of the bladder together with the other usual chemotherapeutic and vigilant nursing methods of keeping the urinary tract in good condition.

In no other patient is nutrition such an important matter. Up to 300 grams of protein may be needed daily to keep the patient in protein balance, and the diet should at all times be rich in caloric and vitamin content.

A brief discussion of the nursing care of decubitus ulcers is given and it is pointed out that many of these ulcers can be most effectively treated by excision or graft, and that once they are healed it is much easier to keep the patient in a state of nutritional balance.

The rehabilitation of the paraplegic patient is concerned first with the problem of locomotion be that by walking with braces or crutches or by getting about in a wheel chair. Important too is the aid which these patients must be given toward psychological readjustment, since their great need is encouragement and the development of self confidence. To keep them merely alive as "living memorials to the skill of medical officers during World War II but to no good purpose" is not sufficient. Each patient is a special problem, and each man is worthy of readjustment insofar as his injury will allow it.

JOHN MARTIN M D

Ellis, V. H.: *Injuries of the Cervical Vertebrae. Proc R Soc M Lond* 1946 40 19.

The author points out the improvement in care and treatment of cervical fractures and dislocations and the material reduction in the mortality rate, now approximating 16 per cent. Reduction of nearly all dislocations can be achieved by manipulation or traction, and open reduction is rarely required.

Skeletal traction is recommended by means of tongs applied to the cranial vault or the zygomatic arches. The importance of damage to the interapophyseal ligament in cervical injuries is stressed and fusion and stabilization of the spines with stainless steel wire is recommended after reduction has been accomplished. The author's experiences in several typical cases are reported individually.

HOWARD A. BROWN M D

Estela, J., and Marrasuela, J.: *Posterior Dislocation of the Lumbosacral Intervertebral Disc (Luxación posterior del disco Intervertebral lumbosacro)*. *Rev. Esp. Ortop.* 1946 3 181.

Two factors are responsible for the fact that the overwhelming majority of dislocations of the intervertebral disc occur in the lumbosacral region the static factor namely the large dimension and height

of the discs in that region and the kinetic factor, namely the weight of the body and the mobility of the vertebral articulations.

In regard to location, two types of dislocations may be distinguished the posterolateral and the central. So-called spontaneous hernias are undoubtedly attributable to repeated minute traumas.

Two groups of clinical pictures may be distinguished. In the first group the symptoms are confined chiefly to the spine the normal lumbar lordosis may be absent and scoliosis or kyphosis may be found. Movements of the spine are painful and pressure on the apophysis of the fifth lumbar vertebra also produces pain. In the second smaller group the symptoms are confined mostly to the lower extremities. Among them the contralateral Lasègue sign and Bonnet's sign (pain produced by forced flexion and adduction of the thigh) deserve attention.

The authors are of the opinion that myelography is indicated whenever the clinical examination justifies the suspicion of a herniated disc. They consider myelography as preferable to an exploratory laminectomy. While the myelogram in posterolateral hernia especially the disappearance of the so-called "axillary pouches" is quite characteristic it is not pathognomonic in central hernia because an extrinsic tumor of the cauda equina may produce a similar picture. However extrameningeal tumors in that region are relatively rare.

So-called intermittent bernias (cog wheel of Anglosaxons) may furnish negative myelograms.

Two varieties of the cauda equina syndrome may be differentiated in one motor symptoms predominate while in the other sensory and sphincteric disturbances are predominant.

In posterolateral hernias the authors employ hemilaminectomy of a lumbar vertebrae, while in central bernias a bilateral laminectomy is unavoidable.

JOSEPH K. NAKAT M D

Erickson T. C., Masten, M. G. and Suckle H. M.: *Intrathecal Use of Penicillin. J Am M Ass* 1946 132 561.

The use of penicillin has produced brilliant results, but there is the possibility of toxic reactions when it is given intrathecally. This report is concerned with 4 cases in which there were severe neurological complications with death in 2. References are made to the literature of similar complications, and the 4 cases are reported in detail.

The first patient had a staphylococcal meningitis and occipital lobe abscess and received 50,000 units of penicillin intrathecally one day and the next day 40,000 units by the same route. Eleven days later, and after the drainage of the brain abscess, a flaccid paralysis developed although spinal block was noted before the second injection of penicillin. Laminectomy revealed extensive arachnoidal adhesions.

The second patient was a child of 2 years with a pneumococcal meningitis who received 15,000 units of penicillin daily for 3 days and a fourth dose after

an interval of a week. Following this an extraocular palsy developed and later a spinal block. Intra-ventricular injection of penicillin coincided with a shocklike state which led to death.

The third case was that of a cerebellar abscess of mixed infection. Ten thousand units of penicillin were injected into the drained abscess cavity with immediate and finally fatal untoward results.

The fourth patient had a pneumococcal meningitis and received 10,000 units of penicillin every 12 hours for 48 hours. The spinal fluid was thick and green and after the first intrathecal injection there was marked retraction of the head, neck, and body from which the 6 year old child finally recovered.

The myelopathies usually appear from 10 to 17 days after the initial intrathecal injection of penicillin with the lesion about at the tenth thoracic level. Irreversible damage may have been done to the spinal cord. Some patients are benefited and then have relapses suggesting encysted infection to which penicillin does not gain access. The reaction may not be local as seen in case 4.

The total dosage and the concentration of the injected solution are two factors concerned in the untoward reactions. The reactions can be minimized by greater reliance on maximal parenteral doses of penicillin intrathecally. Solutions should be of low concentration and a large number of units over 20,000 should be avoided. The intrathecal route should be used as little as possible.

ADRIEN VAN BRUGGEN, M.D.

PERIPHERAL NERVES

Taylor I. M., Hoffman W., and Hayner J. G.: Source of Nerve Autografts in Clinical Surgery. Technique for Their Suture. *Am. J. Surg.* 94:67-700.

The search for a satisfactory means of filling in large defects in peripheral nerves continues. The

purpose of the present study is to indicate the nerves which are usable as autografts. Homografts have been very unsatisfactory. The autografts must be made up of relatively unessential nerves and used in the form of cable grafts. No special difficulty is encountered in the use of (mainly) sensory autografts to fill gaps in motor nerves.

Actually the problem resolves itself into determining the obtainable length and the diameter of the essential nerve to be used. The choice of nerve to be used depends on several factors: ease of surgical exposure, diameter available length, and the degree of disability following its removal. The authors indicate the areas of sensory deficit after removal of the nerves.

Use of the following nerves is proposed: intercostal nerves, sural nerve, lateral femoral cutaneous and posterior femoral cutaneous nerves, saphenous nerve, and medial cutaneous nerve of the arm and of the forearm. All of these are about 3 mm. in diameter and from 12 to 25 cm. are obtainable in each. The diameter of the peripheral nerve containing the gap to be bridged is also shown: for instance, the median nerve at the wrist has a diameter of 3.5 mm., and the length of the gap is 7 cm. The intercostal nerves to be used have a diameter of 1.5 mm. and by squaring these figures the ratio is 12.3 to 2.3. Six strips of intercostal nerve 7 cm. long will be required. The cable graft should be somewhat longer than the gap to be spanned.

Hitherto the problem has been that of a technical means of suturing the cable graft to the injured nerve. This is accomplished by using autologous unmodified plasma as a suturing agent. Tantalum foil cuffs are definitely contraindicated. Suitable apparatus in the form of molds is necessary, and good results have been obtained with the method in experimental animals. The results in man are uncertain but the method should be tried before recourse to orthopedic operations. ADRIEN VAN BRUGGEN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

De Santiago A. P.: Tuberculosis of the Breast (Tuberculosis de la glándula mamaria) *Bol Soc cir Uruguay* 1946 17 205

Because of the infrequent occurrence of tuberculosis of the breast, the author reports 3 cases occurring in women. The disease occurs during the age of sexual activity between the ages of 20 and 50 years and is most frequent in parous patients. It is usually unilateral, predominantly on the right side.

There appear to be five avenues of infection (1) through the ducts, (2) through the skin directly (3) by direct extension from neighboring foci (4) by the hematogenous route, and (5) by retrograde lymphatic spread from cervical or axillary nodes.

From the standpoint of pathologic anatomy the lesions may be (1) acute, miliary (2) nodular (3) disseminated nodular (4) confluent (5) a cold intramammary abscess, (6) sclerosing and (7) an obliterating type.

The problem whether endocrine factors play a role in the production of the various types of the disease is brought up.

In the differential diagnosis cancer is the most important consideration particularly in the nodular and sclerosing types. The author advocates the use of x-rays with nitason (an opaque medium). The prognosis is varied the condition ranging from a mild benign entity to one which runs a fatal course in only 10 or 12 months.

The treatment is surgical and ranges from simple resection to radical mastectomy according to the indications of the lesions and should be supplemented by general measures against tuberculous infection.

Numerous illustrative photomicrographs and sample roentgenograms of breasts injected with radiopaque media are included.

HIRAM T. LANGSTON M.D.

Brachette-Brian D.: Five Cases of Sarcoma of the Female Breast (Cinco casos de sarcoma de la mama en la mujer) *Arch Soc argent anal* 1946 8 35

In 10,000 tissue examinations, 350 mammary tumors were discovered of these 138 were benign and 212 were malignant. Two hundred and seven of the 212 malignant tumors were epithelial in origin and 5 were classified as sarcomas. Therefore the sarcomas made up 2.36 per cent of the malignant mammary tumors and 1.04 per cent of all the mammary tumors.

The cases of sarcoma are presented with case records, photographs of the gross specimen and photomicrographs. These 5 sarcomas were classified as reticulum cell sarcoma, fibrosarcoma, adenofibrosarcoma (2 cases) and adenofibrosarcoma.

HIRAM T. LANGSTON M.D.

TRACHEA, LUNGS, AND PLEURA

Sweet R. H.: Lobectomy and Pneumonectomy in the Treatment of Pulmonary Tuberculosis. *J Thorac Surg* 1946 15 373

In cases of pulmonary tuberculosis it is striking to find with what frequency the hilar structures are relatively free from evidence of active disease. Lymphadenopathy also is rarely encountered except for evidence in the form of calcification of an old infection. The frequent widespread dissemination of the disease throughout the lungs in the early phases of its development is remarkable. In almost all cases the disease is found to be bilateral, and it is often spread throughout all the lobes of both lungs. Only a few of these foci develop into serious lesions but at operation they can be identified as small, yellowish firm nodules which can be seen or felt. In many cases in which apparently new foci of activity develop in the remaining lobes or in the opposite lung one can usually demonstrate that these areas were present but almost imperceptible in the early roentgenograms. These areas are responsible for the so-called postoperative spread of the disease, which is in reality a reactivation of pre-existing small foci.

It is obvious therefore that tuberculosis does not lend itself to surgical extirpation, in the sense that the entire diseased area can be removed.

In the absence of a certain degree of natural resistance no surgical procedure can be expected to succeed in tuberculosis. However no satisfactory method exists whereby this factor can be assessed. Because of this lack of natural resistance, apparently favorable cases present disappointing results and because of its presence apparently unfavorable cases show surprisingly good results.

In both the lobectomy and pneumonectomy groups the greatest number of failures occurred in the cases presenting large cavities with marked pulmonary destruction. The mere fact that a patient develops large cavities in the lungs is evidence that his resistance to the disease is ineffectual. To avoid a high mortality rate and a high incidence of reactivation therefore he should not be subjected to extirpative surgery.

On the basis of the 63 cases in this series it is not possible to say that those in which the disease was considered suitable for thoracoplasty did better in the long run as a group, than they would have if thoracoplasty had been done.

Lobectomy and pneumonectomy in tuberculosis can be performed with a degree of safety which makes it proper to consider their use in the treatment of suitable cases. No absolute indications or contraindications can be applied. The best results followed pneumonectomy in cases of bronchostenosis and thoracoplasty failure, and lobectomy in those

which might otherwise have been treated by thoracoplasty.

Extirpative surgery has failed to solve the problem of management of cases with enormous cavities which do not respond to collapse therapy. Nor is there definite evidence that lobectomy is superior to thoracoplasty with regard to end results.

Because pulmonary tuberculosis is not primarily a surgical disease, the hope for future progress in its management lies in the development of some medicament which will overcome the invading organism and thus prevent further progress of the condition.

SAKUKI KAKI, M.D.

Tosti B., Gramazio, V. and Ingrao, F.: The Surgical Treatment of Large Tubercular Cavities of the Superior Lobe. (Il trattamento chirurgico delle grandi caverne tubercolari del lobo superiore) *Minerva med., Tor* 1946, 37, 459.

In the treatment of tubercular cavities 5 cm. or more in diameter the author found that intrapleural pneumothorax was inefficient and he advised abandonment of this method. However extrapleural pneumothorax is especially indicated in the cases with an active process in which the large cavity is accompanied by other destructive foci within the surrounding tissue of the lung. Extrapleural pneumothorax should be given preference in the cases which necessitate the intracavity aspiration of Mondaldi in preparation for thoracoplasty. Aspiration diminishes not only the toxic manifestations, but also the size of the cavity so that the number of ribs to be resected is smaller. Because cavities would refill if aspiration alone were used and because a rigid large cavity cannot collapse by this method the treatment of choice is aspiration followed by thoracoplasty. Thoracoplasty with the apicectomy of Semb is limited to the cases in which the cavity is not excessively full.

Extrapleural pneumothorax is contraindicated in cases with cavities close to the periphery of the lung and with inflammatory processes in the extrapleural tissues. As the condition of the lesion in the lung improves, the grave problem of re-expansion of the lung with large cavities presents itself.

ARTHUR F. CAPOLLA, M.D.

Triccerri, F. E. P., Langer, L., and Nacario, R.: Bronchial Adenoma (Adenoma bronchialis) *Pressa med. arges* 1946, 33, 307.

This report comprises a review of 12 cases of bronchial adenoma treated by resection (8 pneumonectomies and 4 lobectomies) on the service of R. H. Overholt, Boston, Massachusetts. Since the report in 1946 3 additional cases have been successfully treated. The earliest case was seen in 1933.

The entire topic is reviewed at some length from the standpoint of the clinical picture, diagnosis, pathogenesis, and treatment. The opinions concerning the nature and behavior of these tumors are illustrated in the attitude taken in their treatment.

The possible forms of treatment include (1) irradiation (2) bronchoscopic management, which includes

implantation of radium needles, electrocoagulation, and removal by local resection, and (3) resection in the form of lobectomy or pneumonectomy. These lesions are considered as indications for resection because only in this manner can the frequent extra-bronchial extensions be cured for the potential malignant aspects of the tumor be obviated, and the frequently concomitant and irreversible lung damage secondary to prolonged bronchial obstruction be managed. Irradiation is believed to be of little value, and bronchoscopic management is limited by the hazards of severe hemorrhage and the inaccessibility of the extra-bronchial extensions.

Two of these cases had metastases to the regional lymph nodes.

The extent of resection is dependent on the location and size of the tumor, the extent of the secondary changes, and the associated findings at operation.

Illustrative photomicrographs and roentgenograms are appended.

HERMAN T. LAMONTAG, M.D.

HEART AND PERICARDIUM

Bialock, A.: The Surgical Treatment of Congenital Pulmonic Stenosis. *Ann. Surg.* 1946, 124, 879.

Because, in cases of congenital pulmonic stenosis, the atretic or constricted area is in the pulmonary conus itself it was doubted that incision or partial excision of the stenotic area would result in permanent improvement. Experimentally it was then found that creation of an artificial ductus arteriosus resulted in an increase in the arterial blood oxygen saturation of animals in which a high degree of chronic arterial unsaturation had been produced.

The author discusses the application of this experimental work to human beings in whom the results were much more striking than had been anticipated. Operation in these cases is indicated when there is evidence of inadequate blood flow to the lungs. Of diagnostic aid are the absence of visible pulsations in the lung fields, fluoroscopy and roentgenographic evidence that the pulmonary artery is small in size. There are many borderline cases wherein accurate preoperative diagnosis is difficult, if not impossible. If in these last cases, the patient seems to have a hopeless prognosis without operation, the author believes that exploration is indicated. If doubt still exists after exposure of the pulmonary artery the intra-arterial pressure of this artery is determined with a water manometer. A pressure greater than 300 mm. of water at present, is held to contraindicate anastomosis. Age limits suitable for this operation have not been established. Operations have been successfully done on an infant of 5 months and an adult of 21 years. It is believed that the operation should be performed on subjects between the ages of 2 and 10 years. Absence of cyanosis in children at rest who have little or no tolerance to exercise, requires that arterial oxygen saturation should be determined under basal conditions and immediately after exercise a definite decrease in the saturation after exercise in cases wherein it is be-

heved that inadequate pulmonary blood flow is the cause, makes necessary a consideration of operative intervention.

The most important change in operative technique has been that instead of the approach on the left side of the chest to utilize a subclavian artery for the anastomosis the approach is made on the side on which the innominate is located, usually but not always, the right side. Exposure of this vessel offers a wider choice of vessels for anastomosis and is also of advantage in case the subclavian artery is used because, when the subclavian branch of the innominate is used the angle caused by the anastomosis of this branch is not as acute as when the subclavian branch of the aorta is used. Despite the multiplicity of variations in arteries arising from the aortic arch there has been in every case a systemic artery suitable for anastomosis to a pulmonary artery. Variations in the position and size of the pulmonary artery were fewer than was anticipated. In the occasional case in which the right pulmonary artery is very short, it may be necessary to ligate and divide the vessel and to use the distal end for anastomosis to the end of the systemic artery. If however the pulmonary artery is freed of its pericardial attachments this procedure will rarely if ever be necessary. In evaluating the alterations of oxygen saturation of arterial blood resulting from this operation it is rather surprising in view of the septal defect and the overriding aorta in cases of the tetralogy of Fallot, that the arterial saturation has risen so greatly in many of the patients. The improvement in the general condition of the patients has paralleled the alterations in the blood saturation and the decrease in their polycythemia.

The author's series of cases numbers 110 with 25 deaths a mortality rate of 23 per cent. These figures include all patients who were subjected to operation irrespective of whether or not an anastomosis was done. The surgical procedures used were as follows:

1. Anastomosis between the end of a systemic vessel and the side of one of the two pulmonary arteries was done in 91 cases with a group mortality rate of 18 per cent (16 deaths).

(a) The subclavian artery was used in 46 cases with 4 deaths.

(b) The innominate artery was used in 36 cases, with 11 deaths. Two of these patients were subjected to autopsy, the findings were (1) a single ventricle with insignificant pulmonary stenosis and (2) transposition of the great vessels combined with pulmonary stenosis. The most common cause of death in this group was cerebral anemia or thrombosis.

(c) The end of the carotid was anastomosed to the side of one of the pulmonary arteries in 9 patients, with 1 postoperative death 9 months later.

2. An end-to-end anastomosis was attempted between the end of a systemic artery and the end of a pulmonary artery in 10 patients. This method was used because (1) the pulmonary artery was very short or (2) because the patient was very ill which made haste necessary. In this group there were 4

deaths these latter patients had atresia of the pulmonary orifice and the vessel was too small for a satisfactory anastomosis. In the future attempts are to be made, in similar cases to effect an anastomosis between the end of the systemic vessel and a longitudinal opening in the side of the pulmonary artery. The deaths which occurred in this group of patients were due to

(a) Mistaking the right pulmonary artery upper lobe branch for the main vessel which was very short in 2 patients. The subclavian artery was anastomosed to the end of the small artery supplying the upper lobe. Retrospection suggests that the main right pulmonary artery might have been divided and its distal end used for the anastomosis if the condition had been recognized.

(b) Anastomosis was not done in 6 patients. One of these patients died because of failure to locate the pulmonary artery at operation (it was also difficult to find the vessel at subsequent autopsy) and a second died because the patient's condition was too poor to withstand operation.

Postoperatively, none of the patients had empyema, mediastinitis, severe bleeding from the site of anastomosis, heart failure or a *Streptococcus viridans* infection. There was no significant interference with the circulation of the arm on the side on which the subclavian artery was sacrificed or used for the anastomosis. Weakness or paralysis of the opposite side of the body in patients in whom the innominate or carotid artery was used either had cleared or was diminishing in all who had survived the operation. Despite the fact that some of the operations were performed too recently to allow an evaluation to be made of the results it appears that all of the patients with exception of one (whose too vigorously manipulated subclavian became thrombosed) are improved. It is believed that the artificial ductus in the remaining patients is patent although a murmur cannot be heard in at least one of them.

EUGENE J. ADRI, M.D.

Sweet R. H. Findlay C. W., Jr. and Reysersbach G. C.: The Diagnosis and Treatment of Tracheal and Esophageal Obstruction Due to Congenital Vascular Ring. *J. Pediatr.* St. Louis, 1947 30: 1

The authors report a case of successful surgical intervention in patients whose symptoms were caused by a double aortic arch.

The first case, that of a 3½ month old male hospitalized because of progressively severe paroxysms of coughing and wheezy respirations which began 10 days after birth showed normal concentrations of serum calcium inorganic phosphorus and phosphatase as well as normal wrist roentgenograms. X-ray examination of the child's esophagus, with the aid of barium revealed a posterior indentation at the level of the aortic arch slightly caudal to this there was an indentation of the right lateral margin of the esophagus. Nothing pathognomonic was found by plain chest films in the neck, upper mediastinal shadow or lung fields.

Fig. 1 (Sweet et al)

At operation under ether-oxygen intratracheal anesthesia, an incision was made through the fifth intercostal space on the left side retraction of the pleura and pericardium overlying the great vessels

revealed a right or dorsal aortic arch which arose from the usual location at the base of the heart. This ascended and then curved over the right main bronchus, proceeding posteriorly and behind the esophagus to emerge at the left posterolateral aspect of that structure. Here it was joined by another much smaller vessel which arose from the first described vessel about 1 cm. above its cardiac origin and passed in front of the trachea and esophagus. From this junction the artery descended in the normal course of the descending aorta along the left side of the vertebral column (Fig 1). At approximately the midportion of the anterior vessel or left aortic arch, there arose a long slender artery which extended through the superior mediastinum to the dome of the left chest where it branched into the common carotid, subclavian and internal mammary arteries. This vessel was actually a left innominate artery. A patent ductus arteriosus connected the undersurface of the left arch with the pulmonary artery on that side, at a point approximately 1 cm. distal to the origin of the left innominate artery. The ductus arteriosus, occluded by external pressure without any untoward effect being noted, was divided between two ligatures of braided silk. The ventral component of the double aortic arch was similarly compressed at a point between the innominate artery and the stump of the ductus. The color of the upper extremities remained normal and the radial pulse did not change. The vessel was divided between ligatures at the point of compression. A sudden shift of the great vessels occurred immediately (Fig 1 inset)

Fig. 2

The left innominate artery retracted superiorly and anteriorly. The exposed portion of the dorsal arch receded slightly posteriorly and to the right. The trachea and esophagus appeared to bulge forward and to the left. Postoperatively and following discharge from the hospital the infant's condition improved.

The second case, a male of 9 years had had three previous hospital admissions because of respiratory infections at 9 months (2 admissions) and at 3 years. On his fourth admission he was able to eat only liquids or strained foods and even with these he vomited 2 or 3 times at mealtime. There was audible wheezing when he became excited. He had frequent upper respiratory infections from which recovery was slow. The x-ray examinations on his third admission had shown a prominence of the upper mediastinal shadow on the right. Barium confirmed this displacement and also revealed narrowing of the trachea at the level of the aortic arch posteriorly and on the right, probably due to pressure. The aortic arch appeared to be in normal position but an aortic arch on the right side could not be excluded.

A second operation was necessary in this case because it was found that the normally arising aortic arch instead of following its usual course down the left thoracic gutter curved behind the esophagus into the right chest. A right posterolateral thoracotomy incision was then utilized the pleura being entered through the fifth intercostal space. It was found that the aorta emerged from behind the esophagus at a slightly lower level than that at which it was seen to disappear on the left side. It descended down the thorax along the right lateral margin of the vertebral column curving gently to the left at its distal end so that it went through the diaphragm in the midline. At the point where the aortic arch became the descending aorta, a large artery branched off and was traced to the apex of the thorax. This was an innominate artery which bifurcated to form the right common carotid and right subclavian arteries. Further dissection of the mediastinal structures revealed a vessel connecting the ascending and descending portions of the aorta. It was found to arise from the ascending aorta just above the base of the heart and traversed the left posterolateral border of the superior vena cava. It then passed dorsally slightly superiorly, and to the right passing over the first portion of the right main bronchus at the point of its origin from the trachea. It joined the descending aorta at the level where the right innominate artery arose. The diameter of this vessel was about one-eighth that of the aorta. This was thought to be a persistent right fourth aortic arch. This superfluous segment of the vascular ring was doubly ligated with silk ties and divided, the severed ends separating immediately after division (Fig 2 inset). No ductus arteriosus or ligamentum was found on the right. The postoperative course of this patient was uneventful except for an unexplained tachycardia which gradually subsided after several weeks.

The authors make the point that the observation in infants of respiratory wheezing or stridor even without dysphagia (which is aggravated by deglutition) should arouse suspicion of the presence of a double aortic arch. These symptoms are usually noted shortly after birth, often become aggravated when the infant is fed, are absent during normal sleep and are markedly aggravated by upper respiratory infections. Dysphagia becomes noticeable only when solid food is added to the infant's diet. Usually these infants do not have other congenital anomalies.

The most informative special examination is that of the esophagus following the ingestion of barium.

A study of previously reported cases suggests that an approach on the left side of the chest is the wisest for the surgeon to use because the surviving left fourth arch is usually more amenable to division as the right aortic arch almost always conveys most of the arterial blood. Of help in deciding which pleural cavity is to be entered is the fact that the lateral esophageal deformity usually indicates indentation by the larger of the persistent arches. The visualization of the side on which the main aorta descends along the vertebral column also is of aid in locating the lesser aortic arch, the vessel to be divided which is usually on the same side. The embryology of the reported cases is described and illustrated.

ESOPHAGUS AND MEDIASTINUM

Holt J. F., Haight, C. and Hodges F. J.: Congenital Atresia of the Esophagus and Tracheoesophageal Fistula. *Radiology* 1946 47: 457.

Esophageal anomalies have been classified into three large types:

- 1 Complete absence of the esophagus
- 2 Atresia of the esophagus with an upper and lower esophageal segment, each ending in a blind pouch.
- 3 Atresia of the esophagus with tracheoesophageal fistula (a) with a fistula between the upper segment and trachea (b) with a fistula between the lower segment and trachea (the commonest anomaly) and (c) with a fistula between both segments and the trachea.
- 4 Single tracheoesophageal fistula without esophageal atresia. This type is very rare.

The signs and symptoms of esophageal atresia are fairly characteristic. The inability to swallow fluids, attacks of choking, dyspnea, and cyanosis especially during attempted feeding, and intermittent accumulation of mucus in the pharynx with resultant respiratory obstruction constitute a clinical picture which should not go unrecognized. Inability to pass a catheter into the infant's stomach permits a presumptive diagnosis of partial esophageal obstruction but roentgenological examination is necessary for a positive diagnosis of complete atresia.

Since the anomaly of congenital atresia of the esophagus has now become amenable to surgical

treatment, the various methods of roentgen examination have assumed added significance in the diagnosis and management of the condition, and are discussed in some detail.

Surgical exploration of the anomaly was undertaken in 36 patients of a group of 45 and intrathoracic reconstruction of esophageal continuity was accomplished in 26
SAMUEL KAHN M.D.

Rienhoff W. F., Jr.: Intrathoracic Esophagojejunostomy for Lesions of the Upper Third of the Esophagus. *South. M. J.* 1946 39 928.

Lesions and dysfunction of the esophagus have been a veritable challenge to surgeons throughout the world since Billroth in 1871 demonstrated experimentally that this structure could be successfully removed surgically. The observations of Billroth were soon applied clinically and as early as 1874 Czerny successfully resected the cervical esophagus for carcinoma in that region. Since that time many surgeons have applied themselves not only to the problem of extirpating the esophagus for growths occurring within that organ but to the far more difficult feat of re-establishing the continuity of the gastrointestinal tract following an extirpation of this kind.

In the last decade and a half great advances have been made in what may be termed visceral thoracic surgery in contradistinction to operations upon the chest wall. In addition, patients with disease of the esophagus are not only recognized at a much earlier stage, but are better prepared for operation. The use of parenteral or intravenous feeding, penicillin lozenges, sprays, as well as intramuscular or intrathoracic injections, both preoperatively and postoperatively and the maintenance of a high blood level of one of the various sulfonamides affords the surgeon today a far better operative risk than those of earlier years. Various forms of intratracheal anesthesia, particularly with cyclopropane, maintain the patient in a normal state of oxygenation with a minimal respiratory motion. Sometimes a state of suspended respiration can be maintained for quite long intervals. At this time there is also the free use of blood due to our blood banks which enable one to employ not one but two or even three transfusions at the same time.

Cesar Roux in Lausanne in 1907 made the first attempt at total antethoracic esophagoplasty by mobilizing the jejunum with the mesentery.

The first successful case was the operation performed in Moscow in 1907 by Peter Herzen. In 4 months he succeeded in making an artificial esophagus for a woman who had poisoned herself with sulfuric acid. Herzen added very important improvements to the methods of Roux: (1) unilateral exclusion of the mobilized intestine with anastomosis instead of the bilateral exclusion used by Roux, and (2) the passage of the intestine through a slit in the mesocolon and gastrocolic ligament in order to prevent the possible compression by the transverse colon on the way to the subcutaneous

tunnel. Herzen joined the intestine with the stomach by an anterior anastomosis.

The use of the jejunum as a substitute for the esophagus was given up for a number of years because of the difficulty in maintaining an adequate circulation in the mobilized loop. The method suggested by Roux, that is, dividing the first five vasa recta jejuni, was found to be hazardous to the maintenance of a sufficient circulation to the mobilized loop of jejunum except in quite young individuals who were victims of corrosive strictures of the esophagus. The length of the jejunum necessary to reach from the abdomen over the costal margin to the cervical region above the clavicle could not be obtained unless at least the first five vasa recta jejuni were divided. In 1943 although unfamiliar with the previous work of Roux, the author in the Johns Hopkins Hospital successfully employed the jejunum as a substitute for the esophagus in a patient with a lye stricture running the entire length of the organ. This patient is now completely well and represents the first instance in which the jejunum was transplanted intrathoracically.

It became apparent that the intrathoracic transplantation of the jejunum would permit the use of a shorter length of the mobilized loop of the jejunum than that which would be necessary to encompass the subcutaneous route. Instead of ligating the first five vasa recta jejuni it was found necessary to divide only the second, third, and fourth vessels, which assured an adequate circulation to the entire length of mobilized loop necessary to be employed. In other words sufficient length of mobilized jejunum to run along the entire length of the thoracic cage may be obtained by interfering with the circulation to a far less extent than by the method of Roux. Preservation of the first branch of the superior mesenteric artery is of the greatest importance in maintaining an adequate circulation to the mobilized loop of the jejunum. This first branch is the largest of all the vasa recta jejuni which diminish in size caudalward. To obtain the benefit derived from the preservation of this vessel, transection of the jejunum is performed far below from 30 to 40 cm. from Treitz's ligament.

After division of the jejunum the oral end of the proximal loop instead of the aboral end of the distal loop, is then brought into the chest. Peristalsis does not interfere with the function of this loop.

The importance of the following facts has not been emphasized in the past namely: (1) that the intrathoracic transplantation of the jejunum requires a shorter loop of intestine less mobilization and less interference with the mesenteric circulation than the long loop required by the subcutaneous route and (2) that the transection of the jejunum 30 to 40 cm. from Treitz's ligament permits preservation of the first intestinal branch of the superior mesenteric artery and this insures a more vigorous circulation to the mobilized jejunal loop.

The case histories of 3 patients with different lesions that have been successfully treated by the

Intrathoracic transplantation of the jejunum as a substitute for the esophagus are presented in detail.

The operative technique is carefully described.

The advantages of the use of the jejunum in reconstruction of the esophagus following resection of the latter for carcinoma are as follows:

1. The operation can be divided into two or more stages which makes it unnecessary to subject the patient to an extremely formidable one stage operation as in the case when the stomach is employed.

2. The abdomen can be explored at the time of mobilization of the jejunum for metastases. The importance of this step needs no comment.

3. A gastrostomy may be performed without interfering with the subsequent operative procedure. If the stomach is anchored in this manner its use will be made more difficult whereas the use of the jejunum is not interfered with. The ability to feed the patient by gastrostomy particularly in the presence of extreme dysphagia may result in a far better operative risk because of the general improvement in the clinical condition.

4. In case the cardiac end of the stomach as well as a portion of the esophagus is involved to such an extent that a major portion of the stomach must of necessity be resected then the jejunum is available and can be used in almost any length desired.

It is believed that particularly in patients afflicted with lesions of the upper third of the esophagus the intrathoracic transplantation of the jejunum as a means for the reconstruction of an artificial esophagus has many advantages over other methods advocated in the past. Esophagojejunostomy would seem to be an operation that can be safely performed provided the jejunum is properly mobilized.

Brea, M. M., and Santos, A. A. Mediastinal Fibromyxosarcoma (Fibromyxosarcoma del mediastino) *Rev Acad. argent cir* 1946 30 977

This is a report in considerable detail of a case of fibromyxosarcoma originating in the mediastinum projecting chiefly toward the right. The patient was a female 34 years of age.

Symptoms had been present since 1939, consisting chiefly of chest pain. On December 22, 1943 this lesion situated in the posterior part of the chest was surgically exposed as it was assumed to be a hydatid cyst. However aspiration of the mass indicated its solid nature. In the absence of intratracheal general anesthesia, its removal by an extrapleural approach was undertaken. The fistulized encapsulated tumor was removed. The pleura was torn in the process and an empyema resulted. The patient however made an entirely satisfactory recovery and has remained well for 3 years.

A brief review of the literature is given without a formal bibliography.

The report of this case is illustrated by roentgenograms and a gross and microscopic photograph of the surgical specimen.

HIRSH T. LANGSTON, M.D.

MISCELLANEOUS

Adams, H. D.: Arterial Injuries of the Thorax. *J Thorac Surg.*, 1946 15 365

Technically, the surgical management of some of the more proximal arterial injuries was undoubtedly one of the most hazardous and difficult operations in war surgery. Those in the extremities low enough to permit use of a tourniquet and a direct dissection accomplished in a bloodless field were relatively simple. Those injuries located in the groin, neck, shoulder and chest however required an entirely different approach and surgical management if the patients were to survive their operations. This was true particularly of the arterial injuries of the thorax with its close anatomic relationships in which there is difficulty in obtaining wide and easy exposure.

The author describes in detail his operative treatment of wounds of the mammary and intercostal arteries, the axillary artery and the subclavian and innominate arteries. These wounds were all acquired in warfare.

There were 14 cases of false aneurysm, many in combination with arteriovenous communications as well—6 axillary, 6 subclavian, and 2 innominate. There were no deaths or complications aside from occasional swelling and weakness of the upper extremity. No amputations were necessary and no treatment was required for any unusual circulatory disturbance in this respect. The patients recovered rapidly. Return of function of the upper extremity was variable depending on the degree of the original associated nerve and muscle damage. The lack of circulatory complications was undoubtedly the result of the age of these patients and most probably this procedure could not be done in an older group of patients without more serious circulatory complications.

JOHN J. MALONEY, M.D.

Lahey, F. H.: Pharyngoesophageal Diverticulum. Its Management and Complications. *Ann Surg* 1946 124 617

Pharyngoesophageal diverticula originate at the junction of the esophagus and the pharynx from the pharyngeal dimple, a triangular space bounded above by the lowest fibers of the inferior constrictor and on each side by the oblique fibers of the cricopharyngeus.

If there is any inco-ordination of the swallowing mechanism pressure from the constrictors and the obstruction below from the unrelaxed cricopharyngeus results in a bulge at the pharyngeal dimple.

Recurrent pressure on this weak point causes the bulge to become a sac, a false diverticulum made up of mucosa and submucosa and covered by a few remaining cricopharyngeal fibers.

As the sac enlarges it extends downward and becomes filled with food until it lies parallel with the esophagus with a true sac body, a true neck and a small midline aperture into the true esophagus.

The third stage is the eventual outcome as the sac enlarges and extends further downward into the superior mediastinum.

Each of these stages has its own group of symptoms. Stage 1 usually has no symptoms. An occasional lodging of a dry piece of bread or cereal within the bulge results in attempts to dislodge it by hawking. Operation at this time is neither necessary nor advisable.

The symptoms of the second stage are produced by the sac when it is filled with food which is mixed with air and mucus. The sac moves with swallowing and is compressed against the vertebral bodies by changes in pressure of the sternomastoid, omohyoid and sternothyroid muscles and of the overlying thyroid gland. This produces unpredictable expulsion of food and mucus which may come into the mouth any time during the day or night. In addition audible and frequently embarrassing gurgling may come from the patient's throat with swallowing. Unexpected nocturnal regurgitation may result in inspiration of the sac contents strangulation and the danger of lung abscess.

The third stage presents all the symptoms found in stage 1 with the addition of obstructive symptoms. It is important to understand this obstruction as attempts to pass an esophagoscope, bougie or feeding tube may result in perforation. This obstruction is not due to the pressure of the large filled sac against the lateral esophagus as was first believed but is due to traction on the esophageal wall by the heavy sac. This converts the diverticulum opening into a semitransverse one and the true esophageal opening into a semilateral one. This traction tends to pull the two lips of the opening into the true esophagus together and converts it not into an aperture but into a slit. Attempts at instrumentation cause the tube or esophagoscope to pass into the blind sac and may easily lead to perforation with serious mediastinitis. The author has seen 4 cases of this.

Besides obstruction, complication of an esophageal diverticulum of the pulsion type may be produced by the development of a carcinoma in the wall of the sac. One may be suspicious of this diagnosis when blood tinged mucus is expelled from the sac or x rays show the sac edges to be irregular instead of having the usual sharp clear outline.

Dilatation is the only nonoperative treatment of pulsion esophageal diverticula and is applicable only to the stage 1 type. It is impossible in stage 2 and of doubtful value in stage 1. While dilatation in stage 1 may lessen the obstructive symptoms, it does not delay the increase in sac size unless the noises, or prevent the danger of food or mucus aspiration. All dilatations should be done by passing a bougie over a string previously swallowed.

In the differential roentgen diagnosis of a pulsion diverticulum one must consider a high esophageal web, a high stricture of the esophagus, or a scar of a previously removed esophageal diverticulum. The distinguishing feature of a true diverticulum is the demonstration of its body and neck, and the spill over into the true esophagus of the thin barium mixture after the sac is filled. In the lateral view the

thin line can be seen running from its neck down behind the sac, while in a spherical dilatation the thin line will emerge from the bottom.

The most desirable time to operate on a patient with an esophageal diverticulum is in the early portion of stage 1. At this time the sac is small, there are no inflammatory adhesions, there is a good neck, the opening in the esophagus is small, sac dissection is not difficult, and the patient is free of obstructive symptoms which may affect his health. The second stage of the operation is carried out without difficulty at this time and there is less likelihood of recurrence. Operation during the third stage with a large sac is complicated by inflammatory adhesions, adherence of the sac to the posterior aspect of the pleura, a large rigid mediastinal cavity, the necessity of implantation of the sac on the neck, and a large opening in the esophagus which must be closed.

The patient is fed for 7 days through a Levine tube introduced into the stomach through the nose. Healing usually occurs by primary intention but with large sacs occasional leakage may occur.

These wounds close by granulation and there is no danger of mediastinitis or fascial plane cellulitis when a 2 stage operation is done.

The author first operated upon these cases under local cervical block, but now he uses general anesthesia entirely, mainly ethylene, given with an intratracheal tube. The advantage of being able to find the sac under local anesthesia more easily is far overbalanced by the discomfort of the patient during the long operation.

The author stresses exposure and recommends a longitudinal incision parallel to the anterior border of the left sternocleidomastoid muscle extending from above the level of the junction of the superior thyroid artery and the external carotid down to the sternal attachment of the sternocleidomastoid muscle.

After the incision is made and the platysma cut, the anterior edge of the sternocleidomastoid is freed from the underlying prethyroid muscles. When it is retracted the anterior belly of the omohyoid is identified. This is ligated at its insertion and tendinous part, a d removed. The internal jugular vein is exposed and the inferior thyroid veins passing from the thyroid to it are ligated and divided. When the thyroid is retracted medially the inferior thyroid artery is exposed. This is ligated and divided, as the sac of the diverticulum comes from beneath it (Fig 1b).

The dissection of the sac is then carried out. The sac should be pulled away from the longitudinal esophagus so that the dissection between the inner wall of the sac and the lateral wall of the true esophagus can be carried accurately up to the neck of the sac. This is extremely important. In order to be sure one has completely accomplished the dissection of the neck of the sac, this dissection must be carried completely around the neck until the pale white membrane of the submucosa is shown (Fig 1a).

Fig. 1. (Labey) a, Note in this illustration that the omohyoid has been severed at its tendinous portion and the point of insertion is not shown in this illustration as clamped. The anterior belly is, however, to be removed. Note the retractor pulling the thyroid inward and the retractor ready to pull the common carotid and the internal jugular outward. b, Note in this illustration the inward retraction toward the midline and the outward retraction of the large vessels. The diverticulum sac is completely dissected from its attachment to the longitudinal esophagus and pulled upward. Note the remaining circular fibers of the cricopharyngeal or inferior constrictor muscles about the lower angle of the sac neck. These are to be severed.

There is a tendency for the inexperienced to stop short of complete dissection of the lower angle of the neck of the diverticulum sac. The use of a Berens-Beebe loupe will magnify the field and aid in dissection. If this angle is not completely freed the resulting shelf or ledge will catch food and throw it into the incompletely removed sac which will result in a recurrence.

Fig. 2. a, Note in this illustration the complete dissection of the neck, with the pale white surface of the submucosa. Note the removal of the sling fibers about the neck of the sac at the angle. The sac has been completely dissected from its attachment to the longitudinal esophagus so that it actually hangs by its neck. b, Note again the completely dissected neck with its pale white submucosa and that the sac has now been approximated to the prethyroid muscle. This illustration gives the impression that the stitches have passed through the sac. They have been passed through only the adventitia about the sac but care is taken to see that the needle does not penetrate the sac. This makes it possible to bury the small sac within the wound and to find it easily at the second stage of the operation (Courtesy of J. B. Lippincott Co.)

Dissection of the sac on the right side often is very difficult because it cannot be visualized. There is great danger of unwittingly making a hole in the sac neck at this time. If there is any difficulty or uncertainty about the safety of the procedure, the freeing of the right side should be delayed until the second stage when it can be done just as easily.

Each of these stages has its own group of symptoms. Stage 1 usually has no symptoms. An occasional lodging of a dry piece of bread or cereal within the bulge results in attempts to dislodge it by hawking. Operation at this time is neither necessary nor advisable.

The symptoms of the second stage are produced by the sac when it is filled with food which is mixed with air and mucus. The sac moves with swallowing and is compressed against the vertebral bodies by changes in pressure of the sternomastoid, omohyoid and sternothyroid muscles, and of the overlying thyroid gland. This produces unpredictable expulsion of food and mucus which may come into the mouth any time during the day or night. In addition audible and frequently embarrassing gurgling may come from the patient's throat with swallowing. Unexpected nocturnal regurgitation may result in aspiration of the sac contents strangulation and the danger of lung abscess.

The third stage presents all the symptoms found in stage 2 with the addition of obstructive symptoms. It is important to understand this obstruction as attempts to pass an esophagoscope bougie or feeding tube may result in perforation. This obstruction is not due to the pressure of the large filled sac against the lateral esophagus as was first believed but is due to traction on the esophageal wall by the heavy sac. This converts the diverticulum opening into a semitransverse one and the true esophageal opening into a semilateral one. This traction tends to pull the two lips of the opening into the true esophagus together and converts it not into an aperture but into a slit. Attempts at instrumentation cause the tube or esophagoscope to pass into the blind sac and may easily lead to perforation with serious mediastinitis. The author has seen 4 cases of this.

Besides obstruction, complication of an esophageal diverticulum of the pulsion type may be produced by the development of a carcinoma in the wall of the sac. One may be suspicious of this diagnosis when blood tinged mucus is expelled from the sac or x rays show the sac edges to be irregular instead of having the usual sharp clear outline.

Dilatation is the only nonoperative treatment of pulsion esophageal diverticula and is applicable only to the stage 2 type. It is impossible in stage 3 and of doubtful value in stage 1. While dilatation in stage 2 may lessen the obstructive symptoms it does not delay the increase in sac size, allay the nausea or prevent the danger of food or mucus aspiration. All dilatations should be done by passing a bougie over a string previously swallowed.

In the differential roentgen diagnosis of a pulsion diverticulum one must consider a high esophageal web, a high stricture of the esophagus or a scar of a previously removed esophageal diverticulum. The distinguishing feature of a true diverticulum is the demonstration of its body and neck, and the spill over into the true esophagus of the thin barium mixture after the sac is filled. In the lateral view the

thin line can be seen running from its neck down behind the sac, while in a spherical dilatation the thin line will emerge from the bottom.

The most desirable time to operate on a patient with an esophageal diverticulum is in the early portion of stage 2. At this time the sac is small, there are no inflammatory adhesions, there is a good oock, the opening in the esophagus is small, sac dissection is not difficult and the patient is free of obstructive symptoms which may affect his health. The second stage of the operation is carried out without difficulty at this time and there is less likelihood of recurrence. Operation during the third stage with a large sac is complicated by inflammatory adhesions, adherence of the sac to the posterior aspect of the pleura, a large rigid mediastinal cavity, the necessity of implantation of the sac on the neck, and a large opening in the esophagus which must be closed.

The patient is fed for 7 days through a Levine tube introduced into the stomach through the nose. Healing usually occurs by primary intention, but with large sacs occasional leakage may occur.

These wounds close by granulation and there is no danger of mediastinitis or fascial plane cellulitis when a stage operation is done.

The author first operated upon these cases under local cervical block, but now he uses general anesthesia entirely, mainly ethylene given with an intratracheal tube. The advantage of being able to find the sac under local anesthesia more easily is far overbalanced by the discomfort of the patient during the long operation.

The author stresses exposure and recommends a longitudinal incision parallel to the anterior border of the left sternocleidomastoid muscle extending from above the level of the junction of the superior thyroid artery and the external carotid down to the sternal attachment of the sternocleidomastoid muscle.

After the incision is made and the platysma cut, the anterior edge of the sternocleidomastoid is freed from the underlying prethyroid muscles. When it is retracted the anterior belly of the omohyoid is identified. This is ligated at its insertion and tendinous part and removed. The internal jugular vein is exposed and the inferior thyroid vein passing from the thyroid to it is ligated and divided. When the thyroid is retracted medially, the inferior thyroid artery is exposed. This is ligated and divided, as the sac of the diverticulum comes from beneath it (Fig 1b).

The dissection of the sac is then carried out. The sac should be pulled away from the longitudinal esophagus so that the dissection between the inner wall of the sac and the lateral wall of the true esophagus can be carried accurately up to the neck of the sac. This is extremely important. In order to be sure one has completely accomplished the dissection of the neck of the sac, this dissection must be carried completely around the neck until the pale white membrane of the submucosa is shown (Fig 2a).

Fig. 1. (Lahey) a, Note in this illustration that the omo-hyoid has been severed at its tendinous portion and the point of insertion is not shown in this illustration as clamped. The anterior belly is, however, to be removed. Note the retractor pulling the thyroid inward and the retractor ready to pull the common carotid and the internal jugular outward. b Note in this illustration the inward retraction toward the midline and the outward retraction of the large vessels. The diverticulum sac is completely dissected from its attachment to the longitudinal esophagus and pulled upward. Note the remaining circular fibers of the cricopharyngeus or inferior constrictor muscles about the lower angle of the sac neck. These are to be severed.

There is a tendency for the inexperienced to stop short of complete dissection of the lower angle of the neck of the diverticulum sac. The use of a Berensson Beebe loupe will magnify the field and aid in dissection. If this angle is not completely freed the resulting shelf or ledge will catch food and throw it into the incompletely removed sac which will result in a recurrence.

Fig. 2. a, Note in this and the complete dissection of the neck, with the pale white surface of the submucosa. Note the removal of the sling fibers about the neck of the sac at the angle. The sac has been completely dissected from its attachment to the longitudinal esophagus so that it actually hangs by its neck. b, Note again the completely dissected neck with its pale white submucosa and that the sac has now been approximated to the prethyroid muscle. This illustration gives the impression that the stitches have passed through the sac but care is taken to see that the needle does not penetrate the sac. This makes possible to bury the small sac within the wound a second stage of the operation (C. B. Lahey, J. B. Lippincott Co.)

Dissection of the sac on the right side often is very difficult because it cannot be visualized. There is great danger of unwittingly making a hole in the neck at this time. If there is any difficulty or uncertainty about the safety of the procedure, the freeing of the right side should be delayed until the second stage when it can be done just as easily.

with the added safety that the fascial planes and mediastinum are sealed off. When the sac is completely dissected it is implanted in the wound and in the neck for 7 or 8 days if large. If small its tip is sutured high up to the outer edge of the sternohyoid muscle, care being taken not to put a needle through the wall of the sac.

If the mediastinum has been widely opened a good sized pack is introduced into it and carried up along the edge of the esophagus to the level of the neck of the diverticulum. This is removed 4 days later. Care must be taken not to angulate the esophagus during implantation of a large sac in the wound.

The second stage of the operation can best be undertaken from 7 to 9 days later. As the wound is reopened the finger can be inserted in the old drainage canal and this permits easy separation of the granulation covered internal jugular vein and common carotid artery from the prethyroid muscles, thyroid, and esophagus.

The black silk sutures anchoring the sac to the prethyroid muscle are located and the sac is severed from its attachment. Its neck is easily wiped out with gauze. When the neck has been well freed at the first operation its relation to the true esophagus is easily established at the second operation. In patients with a small sac and narrow neck it can be doubly ligated with chromic catgut flush with the

esophagus. The neck of the sac distal to the ligatures is clamped and the neck severed. A small amount of sodium sulfathiazole is placed over the ligated neck, a cigarette drain layed over this and the wound reclosed.

The author advises complete reopening of the wound at the second stage since closure of the sac posterior to the esophagus may be very difficult. In every case the Levine tube should be inserted through the nose into the stomach at the time of the second operation. All feeding should be maintained for 7 days through this tube to allow the closed esophagus to heal by primary intention.

In suturing a large sac opening in the true esophagus one should be careful not to narrow the esophagus. In one enthusiasm to get rid of the entire sac, part of the right lateral wall of the esophagus may be pulled over and sutured to the left side this would narrow the esophagus. A drain is inserted into the mediastinum and along the edge of the esophagus for 4 days.

The author has had 3 deaths among 209 cases. The mortality, hospital stay and recurrence rate of the one and two-stage methods are about the same. The author prefers the two-stage method because of the safety from mediastinitis and fascial plane infections when occasional leakage occurs.

ROBERT R. BRIDLOW, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Jones, C. M.: Symposium on Gastrointestinal Bleeding. Diagnostic and Therapeutic Considerations of Gastrointestinal Bleeding. *N England J M* 1946, 235 775

Any consideration of bleeding from the gastrointestinal tract holds the immediate implication that the problem may be either medical or surgical. This is of primary importance and must never be forgotten, either in the discussion of the general problem or in the making of decisions in the individual case.

Because of the possible necessity of surgical intervention, gastrointestinal hemorrhage must invariably be considered from three distinct points of view. It must be thought of in terms of the actual site of the bleeding which implies the necessity for accurate diagnosis whenever possible. The mechanism underlying the hemorrhage must also be carefully evaluated so that proper therapeutic measures may be decided on. The third consideration is the condition of the patient who is bleeding. Even before diagnostic or definitive therapeutic measures are undertaken, a decision must be made regarding the urgency of the situation in terms of shock and circulatory collapse.

A clear differentiation is needed between abrupt hemorrhage of shock proportions and minor oozing that, in the long run, may lead to more or less serious grades of anemia but is not an immediate threat to life. In major acute episodes, the immediate concern is the safety of the patient. Even under the pressure of exsanguinating hemorrhage, however, selected diagnostic procedures are indicated if successful definitive measures are to be carried out. At the same time, a knowledge of the hazards involved is essential in arriving at a final decision concerning therapy whether medical or surgical.

The author reviews gastrointestinal bleeding in detail and stresses certain important points. Determination of the site and character of the hemorrhage—that is, exact diagnosis—is essential to proper detailed therapeutic measures. Treatment must be directed toward immediate control of the sequelae of massive hemorrhage and subsequently toward adequate cure or management of the underlying cause. To achieve satisfactory results the close co-operation of a well trained roentgenologist and of a competent surgeon is essential.

JOHN E. KIRKPATRICK, M D

Schatzki, R.: Roentgenological Examination in Patients with Bleeding from the Gastrointestinal Tract. *N England J M* 1946 235 783.

Massive hemorrhage from the gastrointestinal tract, particularly hematemesis, is one of the dramatic events in medicine that deeply impress both patient and physician.

The roentgenologist is hurried with the responsibility of finding the source of bleeding in a patient who is often sick and difficult to examine. If there is no clinical hint regarding the location of the point of bleeding—that is, whether it is in the upper or the lower part of the gastrointestinal tract—a scout film of the abdomen and examination of the large intestine should precede that of the esophagus, stomach and duodenum. A careful study of the small intestine forms the last part of the examination. Usually however the type of hemorrhage indicates roughly which part of the gastrointestinal tract is the source of bleeding and the suspected region should be examined first. Massive hemorrhage in the majority of cases arises in the upper part of the digestive tract and the question to be decided first is when the patient can best and safely be submitted to barium and meal studies.

In the past the tendency was to delay such examination for 2 or more weeks since it was thought that one at an earlier date not only endangered the patient, but also because of his precarious condition furnished somewhat unreliable results. In recent years this attitude has changed and the manifold advantages of early roentgenological examination are recognized.

The author has not hesitated to examine the patient shortly after bleeding has stopped or even during bleeding although he does not examine patients in shock. The examination without any palpation is made with the patient in the horizontal position peristalsis and gravity (turning him from side to side) being used as the means of distributing the barium over the inner surface of the esophagus stomach and duodenum. So-called spot films—that is films taken during fluoroscopy at the optimal moment of filling and projection—are taken whenever they are deemed advisable, and are of great help.

The routine procedure in the roentgenological examination of the upper gastrointestinal tract in a patient who has had a recent hemorrhage is described in detail.

Good clinical judgment and common sense are essential in the selection of bleeding patients for early examination. Obviously a patient should not be examined during clinical shock. It is usually unnecessary to examine one while he is actively bleeding. Blood clots that lie in the stomach handicap the proper interpretation of the roentgenograms although they do not prevent the diagnosis of varices of the esophagus or large ulcers of the stomach or of the duodenum. It appears reasonable to wait for a period of at least 24 or 48 hours after an acute massive hemorrhage.

Any patient in whom early examination has not demonstrated the cause of hemorrhage should be re-examined at a later date when palpation is possible and he is permitted to stand. Some bleeding lesions

are better demonstrated during the early examination and others at the later more convenient and more thorough one. In spite of every diagnostic maneuver known to the roentgenologist the source of bleeding in a certain number of cases will remain obscure.

A few examples have been selected to demonstrate the problem with which the roentgenologist is confronted in dealing with a bleeding patient. A large number of other lesions especially those in the small intestine and colon have been omitted from this discussion.

The roentgenologist plays an important role in the handling of a patient bleeding from the gastrointestinal tract. In most cases he is burdened with the responsibility of demonstrating the anatomic lesion that has caused the hemorrhage and to do so it may be necessary to examine every portion of the gastrointestinal tract.

Indications and contraindications for roentgenological examination soon after a rupture during hemorrhage are discussed. J. M. I. KISSER TRICK, M.D.

Linn, H. W.: An Analysis of Peptic Ulcer in South Australia, Based on a Study of 1,027 Case Reports. *Med J Australia* 44: 649.

The author presents an analysis of 1,027 cases of peptic ulcer admitted to the Royal Adelaide Hospital, Adelaide, Australia during the period between 1930 and 1944. The three main objects of the investigation were (1) to review the incidence, death rate and symptomatology of peptic ulcer in South Australia, and to see if and where these differ from the findings in other localities; (2) to differentiate between gastric ulcer and duodenal ulcer in the light of etiology and diagnosis; (3) to inquire into the incidence and symptomatology of the combined ulcer and stomal ulcer.

The incidence, death rate and symptomatology of peptic ulcer vary the world over. Duodenal ulcer was found to occur in younger people than gastric ulcer, while the proportion of males to females in both gastric and duodenal ulcer was 7 to 1. In the case of ruptured gastric ulcer males predominated in the ratio of 19 to 1 and for ruptured duodenal ulcer 18 to 1. The author is convinced that both gastric and duodenal ulcer are produced by the same etiological factor and that the variation in incidence and rupture rate between males and females may be due to a combination of varying anatomic and physiological factors with differing external and predisposing causes.

The all-over mortality rate was 8.0 per cent. Of these 88 fatal cases, 40 deaths occurred as the result of chronic ulcers, 39 of the patients had had ruptured ulcers and 3 had had acute erosions of the stomach or of the duodenum. In the entire series of 1,027 cases there were 159 ruptured ulcers and 763 chronic ulcers. It can be seen therefore, that the mortality rate for the former is very high.

Fifty per cent of the patient in this survey were alcohol drinkers. This fact would appear to rule out

the regular use of alcohol as a major cause in the etiology of peptic ulcer although it is undeniably the cause of some recurrences of symptoms. Eight per cent of peptic ulcer patients smoked tobacco, but most men in the community do so also hence smoking must be eliminated as a primary factor especially since 20 per cent of patients were nonsmokers. However in a susceptible subject there is no doubt that tobacco is an added irritant. Etiologically no difference could be found between duodenal and gastric ulcer.

Conspicuous by their absence in this survey are references to psychosomatic factors, recurrences coincident with economic and emotional crises, and seasonal variations in incidence. Ruptured gastric ulcer is twice as common as a ruptured duodenal ulcer in South Australia, while the author states, the reverse is the case elsewhere.

The results of test meal examinations reveal a lower incidence of hyperchlorhydria, and a higher incidence of hypochlorhydria and achlorhydria than is usually expected. So much was this so that in any one case the result of the fractional test meal examination could not be taken as in any way aiding the diagnosis. 30.6 per cent of patients with chronic peptic ulcer who had undergone a previous gastrectomy were found to have a stomal ulcer during the 6 years of investigation.

The author makes a plea for similar inquiries to be undertaken in large centers of population elsewhere. HAROLD LAYTON, M.D.

Wick, A. H.: Conservative Treatment of Acute Perforated Peptic Ulcer. *Brit. M J* 1946, 2: 94.

A gradual trend towards conservatism has occurred during the past 25 years in the management of acute perforated peptic ulcer. Having noted the frequency with which upon laparotomy the perforation were found to be already sealed off by adhesions and having observed several times during the course of some 400 gastrectomies the presence of dense sheets of adhesions which were interpreted as being the spontaneous closure of previous perforations, the author followed the lead of Bedford Turner who, in 1915 reported a series of 6 cases of acute perforations which were treated nonoperatively.

During the past year the author has treated conservatively a total of 14 consecutive unselected cases of acute perforation, including 13 duodenal ulcers, 1 gastric ulcer and 1 stomal ulcer. Essentially the treatment consisted of the complete relief of pain by adequate morphine dosage, the prevention of further leakage by intermittent gastric aspiration, and the administration of intravenous sulfathiazole. Upon discharge 11 of the patients were symptom free, although 1 patient subsequently required drainage of a subphrenic abscess, and 1 had a recurrence of severe pain within a month. Two patients died of pneumonia and 1 patient died of subphrenic abscess and uremia.

The author concludes that there is justification for the further trial of conservatism in the treatment

of acute perforated ulcers and pleads that this perforation may be anticipated and prevented by more urgent surgical treatment of chronic peptic ulcers causing severe symptoms

Greengard H Atkinson A J Grossman, M I and Ivy A. C.: The Effectiveness of Parenterally Administered 'Enterogastrene' in the Prophylaxis of Recurrences of Experimental and Clinical Peptic Ulcer *Gastroenterology* 1946 7 615.

A method is described for the preparation of an enterogastrene concentrate of uniform potency and suitable for parenteral injection in the human being. Therapeutic trial on 43 Mann-Williamson dogs and on 58 patients suffering from proved peptic ulcer over a period of years has demonstrated the probability that the material is effective in preventing recurrences during the period of its administration and for some time thereafter as yet of undetermined length.

Röntgenological examination at the inception of treatment revealed that 57 of the patients had duodenal ulcers, 4 had postoperative jejunal lesions, 2 had gastric as well as duodenal ulcers, and 1 patient had a gastric ulcer. Many of the patients reported symptomatic relief within a few days after the injections were begun and most of them were free of distress after 2 weeks. In the remaining few approximately 3 months elapsed before relief from pain and distress was complete. In most instances an interval of from 2 to 5 months was required before evidence of improvement in the condition was manifest on x-ray examination as interpreted by a trained radiologist.

The protection afforded cannot be explained on the basis of the action of enterogastrene in inhibiting gastric secretion, and the true nature of the agent concerned cannot be defined at present.

CHARLES BARON M D

Bruer G J: The Surgical Aspects of Hemorrhage from Peptic Ulcer *N. England J. M.* 1946 235 777

There is a related group of patients who have massive, and sometimes fatal, hemorrhage but who fail to present a demonstrable ulcer. This group of patients has been a particularly discouraging one. Pathologically the information regarding the source or sources of hemorrhage has been meager. At autopsy the pathologist has generally speaking failed to find an ulcer or other causes of hemorrhage.

A study of 337 patients admitted to the hospital because of massive hemorrhage due to peptic ulcer is presented. Of these, 27 (8 per cent) died from hemorrhage—18 without having been subjected to operation, and 9 following operation performed on 31 patients during active bleeding.

On the surgical ward service of the New York Hospital, 49 (15 per cent) of all patients admitted with massive hemorrhage presented a fatal type of hemorrhage and in all probability would have died without the intervention of surgery.

Two hundred and eighty-eight patients (86 per cent) who were admitted because of hemorrhage recovered without immediate or early surgical intervention.

In patients with the fatal type of hemorrhage the location of the ulcer, if duodenal, is on the posterior duodenal wall, and if gastric, on the lesser curvature. The blood vessels causing the hemorrhage are the pancreaticoduodenal and the right and left gastric arteries or their major branches.

In an attempt to differentiate patients with fatal and nonfatal types of hemorrhage the most consistent criteria are failure to improve promptly under a strict regimen of bed rest, moderate doses of morphine, the withholding of fluids and food by mouth, adequate blood transfusions and the recurrence of hemorrhage while the patient is on a strict regimen.

If operation to save life is decided on, it should be done within 24 or 48 hours of the onset of hemorrhage. The mortality in patients operated on early was 10 per cent, whereas that in patients operated on late (after 48 hours) was 70 per cent.

Large amounts of blood administered as transfusions before, during, and after operation are of great value in operations performed for the control of hemorrhage.

Local ligation of the vessels, giving rise to hemorrhage, has not consistently and permanently controlled hemorrhage. Local excision of the bleeding ulcer and gastric resection, including removal of the ulcer, have given the best results.

In patients who recover from hemorrhage on a strict medical regimen, the question of recommending surgery or of continuing a medical regimen is vital. No definite criteria for differentiating those who should be subjected to surgery and those who may properly be continued on a medical regimen have been developed. On the other hand, the occurrence of repeated hemorrhages, the chronicity and unfavorable location of the ulcer, and failure in the past to respond to a medical regimen in persons over 50 years of age, are factors indicating surgical treatment.

JOHN E. KIRKPATRICK M D

Hollaender F: The Insulin Test for the Presence of Intact Nerve Fibers After Vagal Operations for Peptic Ulcer *Gastroenterology* 1946 7 607

This report contains a detailed description of a physiological test for the presence of intact vagus nerve fibers in ulcer patients following any operation designed to interrupt all vagal stimuli to the stomach. The clinical success or failure of such operations is not discussed in this report. The test is based on the production of a degree of hypoglycemia of 50 mgm./100 c.c. or lower. To produce such a hypoglycemia 25 units of insulin are administered intravenously and its production must always be proved by a series of blood sugar determinations. A fractional gastric analysis is performed to determine whether the resulting vagal stimuli set up centrally are able to evoke any secretory response from the stomach.

The validity of this procedure for the purpose stated is supported by evidence derived from studies on dogs with a gastric pouch and on patients.

A positive response to the insulin test—consisting of a distinct rise in the curve for free acidity of the gastric aspirates, accompanying the production of an adequate hypoglycemia—indicated that some uncut para sympathetic fibers still connect the vagus center in the medulla with the stomach. This acidity curve affords no indication of the proportion of such fibers which remain intact reasons for the qualitative character of the test are discussed. A negative response is suggestive but not necessarily conclusive proof that all the vagal fibers which pass to the stomach have been interrupted. First of all, there must be no doubt that an adequate hypoglycemia had been attained and that neither a permanent nor a temporary acidity was present as shown by a fractional analysis with a suitable test meal. Second, in the presence of a gastroenterostomy or a subtotal resection of the stomach the intestinal regurgitation may neutralize a small acid output and thus mask a true positive response.

Such an equivocal result can frequently be resolved by a repetition of the insulin test especially if the dosage of insulin be increased somewhat. Only after these possibilities have been eliminated can a negative response be interpreted to indicate the presence of no uncut vagal fibers.

CHARLES BARON, M.D.

Samak Ludovici, E.: Malignant Lymphogranuloma of the Stomach (Linfogranuloma maligno dello stomaco). *Minor med Tor* 1946 37 115.

The author adds a case of primary lymphogranuloma of the stomach to the 63 reported cases. This condition occurs chiefly in middle life and clinically is almost indistinguishable from cancer. The symptoms include epigastric pain appearing 3 or 4 hours after eating, often accompanied by nausea, vomiting, anorexia nocturnal sweats, and weight loss. Achlorhydria may be present, hematemesis and melena may also occur and lead to death. A generalized brooding of the skin is sometimes observed, with a secondary anemia. The leukocyte count is variable, with eosinophils up to 14 per cent. The temperature is apt to be low. The roentgenological picture closely simulates carcinoma but may show thickened gastric rugae or even concomitant nod in the stomach and intestines suggestive of lymphogranuloma.

The case reported was that of a 60 year old woman in whom the diagnosis of carcinoma was made. Gastric resection was performed and the typical tissue of Sternberg was found to be replacing the mucosa and widely infiltrating the muscular layer. The post-operative course was uneventful and the patient was treated with arsenicals with satisfactory results until 8 months later at which time the symptoms reappeared and a mass was discovered in the epigastrium. Death occurred 3 months after surgery.

EDITH B. FARKSWORTH, M.D.

Hilber, A.: Ulcus Simplex Jejuni. *Acta chir scand* 1946 94 550.

About 100 cases of simple ulcer of the small intestine have been reported in the literature. In 51 of these, the ulcers have been localized in the jejunum. Dyspepsia and frequently melena are the essential symptoms and the condition is rarely recognized prior to perforation. Grossly simple ulcer of the small bowel is similar in appearance to ulcer of the stomach or duodenum. The etiology of the condition is unknown, and by definition, ulcers associated with tumor, syphilis, tuberculosis, foreign body, Meckel's diverticulum and postoperative jejunal ulcers are not included in the group.

In the present article the author reports an additional case of perforated ulcer simplex jejuni which, following excision and suture of the defect, went on to uncomplicated recovery.

WAYNE CAMERON, M.D.

Wilbur, D. L., and Camp, J. D.: Amebic Disease of the Cecum: Clinical and Radiological Aspects. *Gastroenterology* 1946 7 535.

The present report comprises the cases of amebiasis of the cecum observed at the U. S. Naval Hospital, Oakland, California. The authors suggest that with the return of military personnel from areas in which people are heavily infected with amebiasis, it is important that clinicians and roentgenologists be on the alert for signs of this disease.

The syndrome varies widely and masquerades with a variety of clinical pictures resembling those of almost all types of cecal and appendiceal lesions. Symptoms may be absent. In such cases a diagnosis usually had previously been made of acute appendicitis, appendiceal abscess or carcinoma of the cecum. It is important to rule out the erroneous diagnosis of acute appendicitis in such cases because of the disastrous results of surgical therapy in the presence of amebiasis. The mortality of such therapy incident to the Chicago epidemic of 1933 was 40 per cent.

The significant roentgenological changes in the cecum consists of spasm, dilatation, relaxation and abnormal patency of the ileocecal valve. Inflammatory in duration with "coning," and inflammatory tumefactive defects. The earliest lesions are those involving the mucosa and the cecal walls lose their sharp, smooth character and are replaced by a finely granular or irregular contour of the mucosa, which may be associated with varying degrees of cecal spasm.

Cecal lesions of amebiasis were found by barium enema studies in 9 of 37 patients with stools which, on routine examination, contained cysts or trophozoites of ameba histolytica.

In the experience of the authors the most valuable method of examination was the roentgenological study of the colon whether or not symptoms were present or the stool examination was positive. Roentgenological examination was particularly useful in indicating the diagnosis of amebiasis in patients with a history suggesting previous disease of the appendix, and in those with hepatitis or otherwise un-

explained enlarged livers with abscesses of the liver when amebæ or cysts could not be found in the stools or pus

HAROLD LAUFMAN M.D.

Tashiro, S. and Zinninger M. M. Appendicitis: A Review of 936 Cases at the Cincinnati General Hospital Arch Surg 1946 53 545

The present report is the third one in the authors' review of a series of cases of acute appendicitis treated at the Cincinnati General Hospital, Cincinnati, Ohio, since 1915 and covers the five year period from 1939 through 1943.

The incidence of acute appendicitis without perforation showed an absolute and relative increase and the incidence of perforation showed a corresponding and gratifying decrease. A reduction was also noted in the use of catharsis and in the time elapsing between the onset of symptoms and admission of the patient to the hospital. However, negro patients as a group were admitted to the hospital at a significantly later period of illness than white patients and as a group showed a higher incidence of catharsis.

The McBurney incision has been the customary approach to the appendix at this clinic for a number of years. The question of drainage remains unsettled. The incidence of pelvic abscess was greater in patients with perforation when the peritoneal cavity was not drained but the mortality in this group was lower.

The mortality among patients with acute appendicitis without perforation was 0.49 per cent as compared with mortality figures of 0.80 per cent and 1.03 per cent for the first and second series reported from this hospital. The mortality among patients with perforation and generalized peritonitis was 13.77 per cent as compared with 33.9 per cent and 17.2 per cent reported among patients in the two preceding reviews. The mortality for the group with abscess formation was 4.3 per cent as compared with 11.4 per cent and 10.1 per cent for cases included in the first and second reviews.

Penicillin was not used in any case of appendicitis included in this report. Sulfonamides were given to 114 of the 167 patients with perforation and generalized peritonitis with a mortality rate of 11.3 per cent as compared with 18.8 per cent in the untreated group. The mortality among 93 patients with appendicitis and abscess formation was 4.5 per cent and 4.1 per cent respectively for the treated and untreated groups.

The reduction in mortality reflected in this review is attributed at least in part, to an intensive educational campaign begun in Cincinnati in 1934.

EDWARD W. GRUBB, M.D.

Simpson, D. G. Acute Appendicitis in the Aged Brit. M. J. 1946 2 986.

The author states that from 1 to 3 per cent of all cases of acute appendicitis occur in patients over 60 years of age and the mortality in this group is from 25 to 30 per cent. The signs and symptoms in elderly persons are considerably different from the usual

clinical picture in younger patients. With advancing years, the structure of the organ has altered the lymphoid tissue has largely disappeared and fibrous atrophic changes associated with vascular changes are present that cause an inability of the circulation to respond to the demands of inflammation. Hence the devitalized appendix, when subjected to obstruction by a fecolith soon perforates. As the omentum and peritoneum frequently lack their 'pristine ability' to localize the infection, general peritonitis results and a fatal termination is common. Thus the usual sequence of events in appendicitis is altered pain though nearly always present is poorly localized and only becomes intense with the onset of peritonitis. As constipation is frequent, the pain is often misinterpreted as due to this. The general reactions of nausea and vomiting, fever, and elevated pulse rate are not found, and the localizing signs of rigidity, tenderness, and pain on rectal examination are vague and inconclusive or absent. As a result the patient neither feels nor appears ill, and frequently delays seeking advice until peritonitis has developed.

With the onset of perforation pain, distention, vomiting and fever appear and particularly with the presence of a mass an incorrect diagnosis of intestinal obstruction may be made. In one series the misdiagnosis of appendicitis for carcinoma or bowel obstruction was 38 per cent. Elevation of the white count is of help in the differentiation.

In the operative treatment it is recommended that incision be made in the right iliac fossa rather than near the midline to minimize peritoneal contamination. Where the diagnosis is in doubt this route may be utilized well for the performance of a cecostomy to relieve obstruction of the large bowel.

An illustrative case at the age of 85 with survival is discussed.

WAYNE CAMERON, M.D.

Cohen, S. E., and Matthews, B. L.: Diverticuli of the Colon. Surgery 1946 20 823

Attention is called to a type of diverticulum of the colon which heretofore had not been described. The patient underwent a resection of the left colon for what was thought to be an obstructing carcinoma. The specimen revealed, in addition to the usual sacculations of diverticulosis, one long (9 cm.) diverticular structure. Microscopically the sinus space was situated outside the circular layer of muscle. It was lined with a chronic vascular granulation tissue with occasional remnants of mucosal glands still present.

The authors interpret this type of intramural sacculatation as a diverticulum which had its progression through the wall arrested, was turned distally and then was propelled isoperistaltically within the wall of the bowel. When this cavity became filled with feces or gas, the patient developed signs of obstruction. The cloaca of the intramural diverticulum was edematous thereby apparently causing closure and a ball valve or tension mechanism. The authors apply the term 'diverting (intramural) diverticulitis of the colon' to this lesion.

HAROLD LAUFMAN, M.D.

Ochaner, A., and Hines, M. O.: Carcinoma of the Colon: Analysis of 113 Cases. *South S. press* 1946 12 260.

The etiology of colonic carcinoma as in carcinoma elsewhere, is not known except that in many instances the malignant neoplasm originates in solitary or multiple polyps. It is the belief of the authors that congenital polyposis is so definitely premalignant that carcinomatous change is prevented only by removal of the involved bowel or the relatively early development of carcinoma is inevitable. Sites at the flexures which are relative points of fixation are thought to be factors in producing malignant changes in these areas.

Carcinomas of the colon and the rectum are adenocarcinomas and may vary considerably pathologically from a large bulky fungating mass which is likely to be found in the cecum to a relatively small cicatrizing lesion producing complete obstruction of the bowel which is found most frequently in the left colon particularly the sigmoid or to a small polypoid tumor with no encroachment on the bowel lumen. A relatively infrequent type of rectal and colonic carcinoma is colloid adenocarcinoma in which there is an overproduction of gelatinous material. Colloid carcinomas although they occur infrequently are of significance because they usually offer a relatively poor prognosis. As a matter of fact gelatinous tumors of the rectum have been considered by Miles as not being curable by any known means. This entirely pessimistic viewpoint is rarely justified however even though the prognosis is bad.

Gilchrist and David showed that lymphatic involvement in these lesions is much more extensive than commonly considered. By employing a special technique in which the involved bowel and the lymph bearing areas were cleared according to the technique of Spalteholz, they were able to demonstrate malignant involvement of a large number of lymph nodes. The size of the tumor also had little influence on the number of nodes involved. Although the extension is generally upward in cases in which there is blockage of the normal lymphatic drainage retrograde extension may occur. Tumors at the level of the levator ani have a double drainage, i.e., upward along the superior hemorrhoidal artery and also laterally along the superior surface of the levator ani muscle. There can also be direct extension through the bowel and beyond the bowel to the surrounding and adjacent structures. Hepatic metastases must always be considered because of the possibility of the tumor cells getting into the portal system and being carried through that system to the liver.

The sexual relationship in large bowel carcinomas varies according to different statistics. In the authors 113 cases, 52 (45.6%) were males and 61 (54.4%) were females.

The contents of the right colon are fluid, whereas the contents of the left colon are solid. Because tumors of the right colon are bulky and fungating, but do not produce a great deal of narrowing of the

lumen obstruction is relatively infrequent. On the other hand because left-sided lesions are cicatrizing, particularly those in the sigmoid and because the contents of the left side of the colon are inspissated, constipation is a relatively early manifestation. The passage of blood and mucus, an unexplained anemia, in an individual who otherwise is well and who has no symptoms, may be caused by a fungating, ulcerating tumor in the cecum.

The complaint of hemorrhoids or any other rectal disorders requires thorough investigation, because most rectal carcinomas have associated hemorrhoids. In all rectal complaint a malignancy must be considered first. Most rectal lesions are within the last six centimeters of the anus, and these lesions can be detected usually by the examining finger. By means of proctoscopy or sigmoidoscopy it is possible not only to visualize lesions in the rectum and sigmoid but also to obtain biopsies of the tumor.

Röntgenography is of little value in low-lying lesions. Fluoroscopic visualization of the filling of the bowel is essential. All patients with colonic and rectal carcinoma should have double contrast studies in addition to the ordinary roentgenogram following a barium enema.

The treatment of rectal and colonic malignancies might be divided into two types, the preventive and curative. Since many if not the majority of colonic malignancies begin as benign polyps, the recognition of these benign lesions and their complete removal will prevent the development of a cancer. If the polyp is located in the rectum, below the peritoneal reflection it can be removed through the proctoscope. Those lesions above the reflection of the pelvic peritoneum should be operated upon transabdominally and the polyp removed. The curative treatment of colonic and rectal malignancies consists of complete removal of the involved segment of the bowel together with the possible sites of extension both the direct and the lymphatic extensions.

In the presence of obstruction, decompressive procedures must be done as early as possible in preoperative preparation. If this is not done the danger of perforation of the cecum which is the most vulnerable site in a colonic obstruction, is considerable. After the performance of a decompressive cecostomy or colostomy sufficient time must be allowed to elapse for the acute inflammation to subside and for the gut to regain its tone before any resection of the involved segment is attempted.

After the relief of acute obstruction, it is important to re-establish the normal nutritional status. Since many of these patients have lost weight and have been ill for some time they are likely to have a contracted blood volume with resulting hemoconcentration. The ordinary blood studies give false values because they do not represent the amount of the total circulating blood constituents. Sufficient whole blood to re-establish the normal levels of cellular elements, hemoglobin, and protein should be given before operation is contemplated.

Sulfasuxidine and sulfathiazine have been used in the preparation of these patients. Neither of these substances is absorbed readily from the intestinal tract the latter is effective in relatively small amounts.

Whenever possible the operative procedure and anastomosis when done should be carried out aseptically. In abdominal perineal resections the operation is performed almost entirely aseptically, because the bowel is divided by means of the actual cautery between crushing clamps. The clamp on the proximal end of the distal bowel is small enough so that it can be shoved down in the hollow of the sacrum together with the mobilized sigmoid and rectum without any contamination. The obstructive resection is done aseptically and also it is desirable when possible to perform a 'septic' anastomosis when a primary anastomosis is made. In the author's series a resection formed in 37 cases of which 17 (62%) were done aseptically and in 10 (37%) an open anastomosis was used.

Spinal anesthesia was preferred and used with very few exceptions. In the case in which there is some question concerning the resectability or operability continuous spinal anesthesia is to be preferred.

The incision used for right-sided lesions is either a long paramedian or transverse incision. A transverse incision is used for lesions of the ascending colon for sigmoid and descending colon. A transparamedian one which permits a better access to the pelvis. In all right-sided lesions, a right colectomy is done. Unless there is a great deal of inflammatory reaction with fixation of the tumor to the abdominal parietes a one-stage resection of the right colon is preferable. In the one-stage procedure resection of the right colon followed by an end-to-side ileocolic anastomosis is done as a preliminary procedure later the right colon is removed.

Lesions of the transverse colon the splenic flexure descending colon and sigmoid are treated by resection with end-to-end anastomosis or by obstructive anastomosis performed preferably with end-to-end aseptic technique is better than obstructive resection because of the shorter convalescence and the more complete removal of the bowel and its mesentery. In 42 of the abdominal perineal resections with colonic resection was done in 27 (64.4%) and an obstructive resection in 15 (35.6%). Of the resections with end-to-end anastomosis an aseptic technique was used in 17 and an open anastomosis in 10.

Although the authors resect and re-establish continuity of the bowel in sigmoidal lesions with the exception of those at or near the rectosigmoid junction, they believe that this procedure is not justified in the low-lying lesions. They have used it in only one patient in whom a primary anastomosis

was done for a rectosigmoidal lesion. Fortunately it was the first case in which the conservative procedure was done, and although it is believed that a fataly occurred unnecessarily in this case it is the authors opinion that had an abdominoperineal resection been done originally the man would probably have been cured. The care of the colostomy necessitates the taking of an enema every 2 or 3 days is a relatively cheap price to pay for the cure of a malignant disease as contrasted with the price of a few months to a year's normal sphincteric control to be paid for with one's life.

Wide resection of the mesentery and the lymph bearing area is essential. High ligation of the superior hemorrhoidal vessels and removal of the accompanying lymph nodes is necessary in rectosigmoidal and rectal lesions.

In 103 of the authors cases, the tumor was graded according to Broder's classification, grade I 12.6 per cent, grade II 51.4 per cent, grade III 35.8 per cent, grade IV 1.9 per cent.

In the entire group of 113 cases, 96 resections were done (84.8%), 105 (92.8%) left the hospital alive whereas 8 (7.1%) died in the hospital. In 18 cases in which the right colon of the tumor was removed for cancer of the colon, the mortality rate following operation for cancer of the colon varies according to the location of the tumor which a portion of the left colon was resected (in 4 cases as a palliative procedure and in 20 as a curative procedure) there were 2 deaths (5.6%). In 48 cases as an abdominoperineal resection was done usually in which rectosigmoidal resection was done usually were 2 deaths (4.1%). Although there may be some question about the advisability of a palliative resection in malignant lesions of the colon and other viscera this procedure seems perfectly justifiable to us because not only is the patient relieved of the undearable symptoms incident to an ulcerating tumor of the bowel but following the removal of a primary tumor the growth of metastatic lesions is less rapid than before the extirpation of the original tumor.

In the authors series of cases the resectability of lesions in the right colon and those of the rectosigmoid were approximately the same 81.8 per cent and 84.5 per cent respectively. The resectability of lesions of the left colon exclusive of the rectosigmoid and rectum was 65 per cent, due to the fact that in this group extension to the abdominal parietes was present in a much higher incidence which many times precluded resectability.

Although re-establishment of the continuity of the bowel in low-lying lesions has become a popular procedure the authors believe that in any lesion except the extremely small ones in which there can be no extension distally abdominoperineal resection is the operation of choice, and that as long as attempts are made to preserve the sphincter the recurrence rate and death rate from carcinoma will continue to be high.

D Allaines, F. and De Vernejoul, R.: Conservation of Sphincter Function in the Operative Treatment of Rectal Carcinoma (Conservation de la fonction sphinctérienne dans la cure opératoire du cancer du rectum) *J. chi. Par.* 946, 62: 274.

In rectal carcinoma one of two operations can be done: either the mutilating amputation, or resection of the rectum with conservation of the sphincters. A considerable number of surgeons reject the resection because of the supposedly greater risk of recurrence. However, the recent work on the anatomy of the lymphatics makes it possible, in appropriate cases, to conserve the sphincter without increased danger of metastases or recurrence. Of equal importance is an exact knowledge of the anatomy of the nerves of the sphincteric apparatus.

Although the resection is by far preferable to the amputation, it is applicable only under certain conditions. The resection should be as extensive as possible, at least 15 cm. above the superior border of the tumor and at least 5 cm. below the inferior border. As a certain portion of the anal canal should be left intact to assure a good functional effect, the operation is possible only if the inferior border of the tumor is at least 9 or 10 cm. distant from the anus. It is important to save not only the sphincter muscle and its nerves but the mucous membrane, if possible, to an extent of at least 4 cm. as the mucosa possesses a specific sensibility indispensable for the mechanism of continence. Only if the resection has to be done rather close to the sphincter must the mucosa be sacrificed (technique of Hochenegg, modified by Babcock and Bacon).

Another point of great importance is the radical ablation of the lymphatics. The recent literature on the invasion of the lymphatics in rectal carcinomas indicates that they have to be examined and removed, often as far as the inferior mesenteric trunk.

The authors discuss the different methods of conservative operation: abdominal, transsacral coccygoperineal, transanal, and transvaginal resection. In the transanal and coccygoperineal methods it is essential to conserve the motor nerves of the external sphincter at least on one side. A number of statistical papers are quoted to show that resection gives better results than amputation of the rectum, not only functionally but also with regard to the post-operative mortality and the incidence of recurrence and metastases. WENNER M. SOWITZ, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Rehfsuss, M. E.: The Etiology of Cholecystitis. *Gastroenterology* 1946 7: 605.

Biliary tract disease is now known to be the most common form of digestive disturbance affecting the upper abdomen in later life, as many as one-half of the individual over 50 years of age are afflicted. There is no unanimity of opinion as to the cardinal factors in the production of biliary tract disease or the mechanism by which they operate. Only by

correlating a large number of careful prospective studies with anatomic and histologic examinations of the organ can we hope to reach more exact conclusions.

Clinical and experimental observations have supported the possibility of several active factors in the etiology of cholecystitis. These are infection, alteration of the gall bladder contents (particularly the bile salts), reflux of the pancreatic juice, lesions of the cystic duct (probably secondary), dissemination of bacteria and their toxins through lymphatic, arterial, or venous channels, and sensitization.

The author briefly cites the evidence for and against each of these factors and reviews the literature pertaining to each one.

The author then describes his work on producing experimental cholecystitis by injecting bacteria. He has demonstrated that every form of human cholecystitis can be obtained by experiments in which bacteria are injected. Histological studies of the experimentally diseased gall bladders show that any or all layers of the wall can be affected; the mucosa and submucosa seem most vulnerable while the muscularis seems to be the least vulnerable. This is true in human cholecystitis. Originally the author was able to produce experimental cholecystitis in only 22 per cent of his series, but later by altering his technique and giving more frequent inoculations over longer periods, he increased the incidence to 63 per cent. In about 10 years of experimentation he has observed the effects of a single antigen, the nonhemolytic streptococcus, in nearly 700 animals.

It appears that cholecystitis can follow a transient bacterial infection and that subsequent changes emphasize the fact that structural damage of various grades may follow relatively few inoculations. A chronic lesion may result from a single injection if its effect is sufficiently severe. It has been the author's experience that repeated injections over months have resulted in a marked increase in the chronic lesions. If the injections are stopped the lesions may be arrested.

Bacterial infection would seem to be the most likely condition capable of inducing an acute change with tissue destruction in a gall bladder in the absence of calculi. There is no indication that any particular strain of bacteria is to be incriminated in the production of cholecystitis.

In experimental cholecystitis, the antigen is not specific for the gall bladder but may produce lesions in the joints and some of the viscera. The evidence indicates that the bacteria or their toxins may localize in any or all parts of the biliary tract. The author is unable to state the nature of the action, whether it is a protoplasmic poisoning, necrosis of the cells, a profound disturbance in cellular chemistry or enzymic activity.

Therapy of any kind should be directed toward the arrest of the acute lesion and control of the contributing factors by combating infection, regulating the metabolic mechanism, correcting biliary stasis, and preventing additional changes which might fur-

then damage the organ. If these measures fail, we then have recourse to surgery.

The dietary approach is of primary importance in therapy since by reducing the amount of fat in the diet one decreases the demands on the organ during inflammation and infection. Detection of the injurious agent such as infection toxin or allergy and its control are important. The author is convinced that many of the systemic infections, virus diseases and local foci in sinuses and tonsils are important. If these are restrained general systemic resistance is encouraged. Penicillin and sulfonamides aid in controlling acute biliary infections. Carefully supervised vaccine, filtrate and other forms of bacterial therapy should be considered. Many measures to modify the bile entering the gall bladder can be employed. To combat stasis the bile should be fluidified.

The author believes that cholecystitis may be an acute process but it is more likely to be due to mild repeated infections acting slowly upon different parts of the gall bladder wall. Such changes may bring about or favor undue concentration of certain elements of bile or produce a pancreatic reflux. It is also possible that bacterial sensitization may play a role.

ROBERT R. BROZLOW M.D.

Elman, R.: Surgery in Acute Pancreatitis. *Gastroenterology* 1946 7 656

Because of the confusion existing in the minds of most clinicians as to whether acute pancreatitis should be treated medically or surgically the author has prepared this article. He defines acute pancreatitis as a primary inflammation of the pancreas sometimes associated with biliary disease but not the type secondary to mumps, diabetes, arteriosclerosis, nephritis or alcoholism. The disease usually has an acute stormy onset with severe abdominal pain in an otherwise healthy individual.

In reviewing the literature on acute pancreatitis the author recognizes three distinct periods. In the early period before 1900, practically all cases were observed at autopsy. Only one type of disease, hemorrhagic pancreatitis, was recognized before death, and the pathological changes were classically described by Reginald Fitz in 1889. In the second period, the early decades of the present century the disease was encountered at operation, often performed without a definite diagnosis. There was a high mortality (50%) and as time went on the trend was toward more conservative treatment. The third period began 10 or 15 years ago when medical treatment was given in view of the high operative mortality.

Much of the confusion in the literature is probably the result of the existence of at least two types of the disease, each strikingly different. Zieppel, in 1922 first described a type of acute pancreatitis not necessarily fatal and not accompanied by necrosis or hemorrhage. The author believes this was an early stage in the development of true pancreatic necrosis which for some reason was aborted. The

findings at operation were confirmed by many later surgeons, and it became obvious that the mortality varied greatly and depended on the type of pancreatic lesion present.

The uncertainty in making a bedside diagnosis of acute pancreatitis has led to difficulty in evaluating results of therapy. It was not until 1929 that the diagnostic use of the serum amylase test established the diagnosis of pancreatitis and tended to clear some of the confusion. It then became clear that many patients with acute abdominal symptoms which subsided rapidly and spontaneously actually suffered from pancreatitis as described by Zieppel. Unfortunately the serum amylase test will not differentiate between the two types of acute pancreatitis mentioned. More accurate data are necessary in order to evaluate the effectiveness of conservative as against operative therapy.

The author reviews his experiences with 17 cases of pancreatic necrosis as shown at autopsy or operation. Of his patients only 1 survived and this patient was operated on. Seven patients entered the hospital with profound circulatory failure and died soon afterward. It was doubtful if any form of therapy would have been successful in this group of patients.

Elman recommends routine serum amylase determinations of all patients with acute abdominal disease. The test takes a little over 30 minutes and shows high values in all patients with acute pancreatitis unless the patient has been sick for many days. Acute parotitis will also give high values. The problem of differentiating acute pancreatic edema from necrosis is not easy. About 80 per cent or more of the cases will prove to be of the interstitial or edematous type or occasionally of the subacute type and such conditions may be expected to subside spontaneously.

The necrotic type may show three clinical features: (1) the appearance of true circulatory impairment or shock, (2) the tendency for manifestations to be those of a spreading perforative peritonitis and (3) the failure of the pancreatic necrosis to subside.

In suspected cases of necrosis operation should be seriously considered unless, of course, conservative therapy is less likely to be followed by a fatal outcome. There is slight evidence that suppurative pancreatitis has occasionally healed without operation but it seems justifiable to assume that extensive necrosis of the pancreas should be looked upon as a perforating lesion leading to suppurative or spreading peritonitis. As such it inevitably would require surgery even if only for drainage of the site of perforation, the lesser peritoneal sac.

Operation to be adequate must provide satisfactory drainage of the pancreas. It is doubtful if any incision into the organ is justified. There is evidence that cholecystostomy diverting bile from the common duct to the outside may be useful. Extensive procedures such as cholecystectomy or common duct drainage prolong the operation and increase the mortality. Operation should be associated with

nonoperative treatment such as gastric suction, both blood and plasma transfusions, and chemotherapy.

The view that acute pancreatitis is universally a nonoperative disease should be abandoned. Operation probably is not indicated in a vast majority of cases. Once the diagnosis is made by the aid of the serum amylase determination each case should be carefully evaluated. Those obviously subsiding present no problem. Should the acute manifestations not subside even though the serum amylase falls, the patient may be suffering from pancreatic necrosis and may require operative drainage of the lesser peritoneal sac. Even patients admitted in profound circulatory shock must be considered as possible candidates for surgical therapy. Just when operation is to be performed cannot be categorically stated, but when pancreatic necrosis is present, operation must be considered to avoid death if possible.

Pancreatic necrosis is to be differentiated from acute edematous pancreatitis and indicates actual destruction usually with hemorrhage into, and gangrene of the pancreatic parenchyma. Fat necrosis may be seen with both types but when this is extensive and involves the greater omentum it is nearly always associated with a true necrosis of the pancreas.

The answer as to whether acute pancreatitis requires surgical or medical treatment must be based on the differentiation between acute pancreatic edema and necrosis. This can be decided only by a careful study of the patient's clinical progress.

ROBERT R. BLOXLOW, M.D.

Whipple, A. O.: Radical Surgery for Certain Cases of Pancreatic Fibrosis Associated with Calcareous Deposits. *Ann Surg* 1946, 124: 991.

The author records 3 total pancreatectomies and 3 other radical procedures with the removal of a large part of the organ for intolerable pain associated with pancreatic fibrosis and calcareous deposits and pancreatic calculi. A history of acute pancreatitis or of chronic alcoholism is common. Disturbed carbohydrate metabolism in the form of mild diabetes is found in about a third of the cases. The same is true of abnormal fat digestion and abnormal stools. Mild pain in the epigastrium is present in the majority of the patients. In some patients the pain is so severe and constant frequently radiating through to the back, as to be intolerable.

The most important laboratory examination is a plain film of the upper abdomen to demonstrate the presence and extent of the calcareous deposits which may appear in the head, the body, or the tail of the pancreas or the entire organ may be outlined by the calcareous material. Next in importance is the finding of a marked deficiency in one or more of the pancreatic ferments, as determined from duodenal aspirations with the administration of methyleyl chloride.

The extent of removal of pancreatic tissue in these radical procedures is determined by the part of the organ showing the calcareous material as seen in roentgenograms, and the amount of fibrosed tissue.

The author states that all of these patients require transfusion therapy during and after operations. The close co-operation of an internist experienced in the treatment of diabetes before and after operation is essential.

ELMER C. ROYMEYER, M.D.

GYNECOLOGY

UTERUS

Figarella J Surgical Treatment of Prolapse of the Uterus (Le traitement chirurgical du prolapsus utérin) *Gyn. édit. Par.*, 1946 45 110

In many cases the operation for prolapse of the uterus gives good results in the beginning but recurrences take place after a few years. The author discusses a series of 77 cases in which prolapse recurred after surgery had been done with good primary results.

One cause of recurrence is incomplete operation. There are three lesions involved in a prolapse: descent of the uterus, cystocele, and relaxation of the perineum. The descent should be corrected by a fixation of the uterus to the anterior abdominal wall, the cystocele by anterior colporrhaphy, and the perineal relaxation by posterior colpoperineorrhaphy. All three operations should be done in every case.

The second cause of recurrence is a lesion complicating the prolapse. The most important lesions are hypertrophic elongation of the cervix, endometriosis, and tumors of the uterus.

Finally faulty technique or poor preoperative and postoperative care may be responsible for recurrences.

The choice of the kind of operation to be done (Schauta, Wertheim, Le Fort, Halban, Bouilly) depends on the age and on the kind of lesion in the individual case. Patients with hypertrophic elongation of the cervix should be treated by the Bouilly operation.

WERNER M. SOLMITZ, M.D.

Gleadell, L. W. The Surgical Treatment of Myomas of the Uterus, with Particular Reference to Myomectomy. *Austral N. Zealand J. Surg.* 1946 16 30.

The present report concerns the experience of the author in the surgical treatment of 376 patients with uterine myomas, of whom 66 were subjected to myomectomy.

The indications for surgical treatment were as follows: (1) size of tumor—the patient is operated upon if the abdominal enlargement causes embarrassment; (2) rapid increase in the size of the tumor; (3) pain and bleeding after the menopause; (4) secondary anemia; (5) certain cases of sterility.

Factors influencing the selection of cases for myomectomy were:

1. Age of the patient. In many instances the length of time the patient had been married and her desire for children were considered more important than age.

2. The number of tumors. The fewer the number the more acceptable is the patient for myomectomy.

3. The situation and size of the tumors. The site except for central cervical tumors, does not matter.

4. Pregnancy. Interference is rarely indicated during pregnancy. Cesarean hysterectomy is a safer procedure than cesarean section and myomectomy.

Factors which are believed to be unfavorable to myomectomy are:

1. Adnexal pathology. Cystic ovaries may be resected and neoplasms removed at the time of myomectomy, but tubal plastic procedures are contraindicated.

2. Suspicion of malignant disease.

With regard to operative technique, the author states that careful asepsis is important; the vagina is prepared with zephiran 1 to 400 and Bonney's blue is injected into the uterine cavity. Absorbable sutures are preferred and the dead space must be completely obliterated. An anterior incision is preferable because it can be peritonealized more completely. The uterine cavity may be opened to reach tumors of the posterior wall unless they are subperitoneal in location, in which event a posterior incision may be made. The vesicouterine fold may be used to cover the anterior incision, or the round ligament may be sutured over it. The posterior incision may be covered by the round ligament, the pelvic colon, or the mesosigmoid.

The results of myomectomy were as follows:

Of 31 patients who had complained of menorrhagia, 18 were cured of 15 patients who had been sterile and who tried to become pregnant after operation, 9 conceived; patients with abdominal swelling were relieved of 14 patients who had complained of pain, 12 were relieved of 10 patients with dysmenorrhea, 6 reported improvement; 2 of 4 patients who had had repeated miscarriages were delivered of full term infants, and 1 patient was relieved of dyspareunia.

Three of the 66 patients (4.5%) who were subjected to myomectomy developed symptoms requiring further surgery. There were no deaths. Fifteen patients had febrile postoperative courses due to chest complications, wound infection, intestinal obstruction, or bladder injury.

J. ROBERT WILLSON, M.D.

Cusmano, L. Clinical and Statistical Notes on Cancer of the Cervix of the Uterus (Note clinico-statistiche sul cancro del collo dell'utero). *Ginecologia*, Tor. 1946 12 249.

During the past 12 years, from 1933 to 1944, inclusive, 7,666 gynecological cases have been admitted to the author's clinic at the University of Parma. Of these, 367 or 4.77 per cent, were carcinomas of some part of the uterus and 281 or 3.66 per cent were cancers of the cervix. Details are given in regard to the disease, the age of the patient, the number of childbirths she has had, her civil status, and her hereditary tendencies. The cases are then divided into three groups: those treated surgically (85 or 30.24 per cent), those treated first with

radium therapy (125 or 44.42 per cent) those treated first with roentgen therapy (59 or 20.99 per cent) and those treated only medically (12 or 4.27 per cent).

Tables are given showing the immediate and late results in all of these cases.

Among the 85 cases treated surgically by Wertheim a amplified hysterectomy there was an immediate mortality of 7 or 8.2 per cent. The results were followed up to 5 years after operation in 39 cases, and among these there was absolute cure in 19, or 48.71 per cent. In 4 there was death from the operation and in 16 death within 5 years after operation but among the latter, death occurred from intercurrent disease in 4 and from recurrence in 12; therefore the mortality from the latter cause was 30.76 per cent.

Among the 125 cases treated with radium there was death immediately after the operation in 5 or 4 per cent. Among the 48 cases followed up for 5 years there was cure in 16 or 33.3 per cent while the remaining 32 patients died within 5 years of operation.

These statistics indicate that changes should be made in the usual method of treating cancer of the uterus: radiotherapy should be given in beginning cases of cancer and those still limited to the uterus, and radiotherapy should precede surgical treatment even in the more advanced cases.

ALBERT G. MORROW, M.D.

Scartozzi, C.: On the Treatment of Cancer of the Cervix (Sul trattamento del cancro del collo dell'utero). *Minerva med. Tor.* 1945, 37, 350.

Five hundred cases of cancer of the cervix observed at the Institute of Surgical Pathology of the University of Torino are reported by Scartozzi. Only operable cases were included in the series, inoperable ones being referred for irradiation treatment. All patients were thoroughly examined prior to surgery in order to determine accurately the extent of the lesion. The operation performed was the classical Wertheim. Postoperative irradiation of the pelvis was found to be of value and therefore was regularly practiced.

Conditions did not permit follow-up studies. It can be stated however that the prime mortality was extremely low and that many patients were known to be in good health 7, 8, 9 and even 20 years after the surgical intervention.

EDITH B. FARNSWORTH, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Blanchi P.: The Significance of the Microcystic Ovary in the Fetus (Sul significato dell'ovale microcistico). *Riv. ital. gine.*, 1945, 23, 30.

The histopathological findings of a fetus at term are described with particular respect to the ovaries which were approximately twice the normal size and contained follicles and follicular cysts. A precocious differentiation on was also noted in the cellular elements of the hypophysis. Bringing his discussion upon these

observations as well as upon accepted concepts of the hormonal relationship between the hypophysis and ovary the author proposes the following hypothesis:

1 There exist in the neonatal ovary possibilities of follicular maturation characterized by a certain maximum point.

2 That maturation may proceed so far as to approximate a pseudoluteal phase without showing migratory movement of the follicle toward the surface of the ovary.

3 Microcystic degeneration is an involuntary process characteristic of such abnormally developed follicles, the end result of which is atresia.

4 This anomalous behavior of the ovary is secondary to an augmented activity on the part of the anterior lobe of the hypophysis.

5 This sequence of events is in turn the probable result of a functional deficiency of the placenta which gives rise to maternal and fetal compensatory actions.

EDITH B. FARNSWORTH, M.D.

Nicosi-Casimiano, G.: Postclimacteric Metrorrhagia and Malignant Tumors of the Ovary (Metrorragie postclimateriche e tumori maligni dell'ovulo). *Riv. ital. gine.* 1945, 3, 364.

Three cases of metrorrhagia resulting from a malignant tumor of the ovary are reported. In all 3 the histological diagnosis was adenocarcinoma with hyperplasia of the endometrium. The author reviews the course of opinion concerning the pathogenesis of endometrial hyperplasia and hypertrophy and corroborates the theory that they are the result of the production of folliculin in irregular quantity and rhythm. Such production is postulated as being stimulated directly or indirectly by the attacked ovary.

The precocious appearance in the cases reported of postclimacteric bleeding before the presence of an ovarian tumor could be clinically determined, is emphasized, and the recommendation is made that metrorrhagia be considered as a potentially malignant sign until all necessary measures be taken to establish the underlying cause. As a reliable routine the author suggests diagnostic curettage to exclude early evidence of malignant degeneration in the endometrial tissue with fortnightly pelvic examinations to determine any increase in the size of the ovaries and prompt exploratory laparotomy on the earliest indications.

EDITH B. FARNSWORTH, M.D.

Vare P.: Connective Tissue Tumors of the Ovary (Ueber Bindegewebsgeschwulste des Eierstocks). *Ann. chir. gyn. fenn.* 1945, 35, 112.

Among 653 cases of tumors of the ovary the author found connective tissue tumors (fibromas and sarcomas) in 36 cases. Frequently it is difficult to differentiate these neoplasms from granulosa cell tumors. The tumors occurred at all ages, before as well as after the menopause; they were nearly always unilateral and their size varied from that of a pigeon's egg to that of a man's head. Thirty were fibromas and 6 sarcomas. They never caused any hormonal disturbances. Ascites occurred in 17 per

cent of the fibromas and in 33 per cent of the sarcomas. Adhesions were rare in the fibromas but rather frequent in the sarcomas. The prognosis was good, even in the sarcomas. All of the patients were free from symptoms 5 years after the operation.

WERNER M. SOLMITZ M.D.

Nobili L.: Neoplasms of the Broad Ligament: A Critical Review of the Literature with a Report of 3 Cases (Le neoplasie del legamento largo Rivista di ginecologia e ostetricia contributo personale di tre casi) *Riv. ital. ginec.* 1945 28 312

Three cases of primary sarcoma of the broad ligament are reported. A review of the literature brought to light 21 adequately documented cases of such tumors originating in the broad ligament of which Nobili adds his 3 under the histopathological diagnosis of (1) polymorphous fibromyxosarcoma (2) fibrotic sarcoma and (3) fibrosarcoma respectively. These neoplasms occur more frequently in individuals between the ages of 30 and 50. Their form is ordinarily round or oval and their surface smooth or finely nodular. Their consistency is that of dense elastic tissue and their weight may reach 113 kgm. The varieties of sarcoma in order of frequency are pure sarcoma, fibrosarcoma, chondrosarcoma, sarcomatoid myoma, telangiectatic sarcoma, pseudomyoma with fibromyxosarcomatous degeneration and fibrotic sarcoma. Metastases were found in 30.4 per cent of the cases, but no characteristic site of the metastases was indicated. The symptomatology of these tumors is ill defined and the diagnosis is made on pelvic examination.

Although these tumors are highly malignant histologically the clinical course appears to be somewhat more benign and the cases which constituted the 30 per cent mortality rate were those in which surgery was undertaken at such a time when the large size of the tumors and the presence of adhesions presented special mechanical difficulties.

EDITH B. FARNEWORTH, M.D.

MISCELLANEOUS

Collins, C. G., and Nelson E. W.: Phlebotrombosis and Thrombophlebitis in Gynecology and Obstetrics. *Am. J. Obst.* 1946 53 946

To emphasize their full importance the complications arising from intravascular clotting in gynecologic and obstetric practice have been reviewed by the authors. A study of the records of all deaths, and of autopsy records when autopsy was present in 50 of the 536 deaths from all causes exclusive of abortion, that occurred in 32,198 admissions to the gynecologic service at Charity Hospital in New Orleans during the period from July 1, 1939 to January 1, 1946.

The authors maintain that by simple preoperative and postoperative measures the incidence of intravascular clotting either aseptic or septic can be lowered and in this way a number of deaths and dis-

abling and disfiguring sequelae can be prevented. The routine postoperative or postpartal examination of the patient's legs is as important as examination of the abdomen. No complaint of thoracic pain, pain in the leg or swelling of the leg should be casually dismissed.

Patients with pelvic tumors and unilateral or bilateral edema of the legs should be considered as having phlebotrombosis of the deep veins of the extremity or pelvis until otherwise proved. One should be careful about ascribing the edema or swelling to pressure produced by the growing tumor. In all cases in which phlebotrombosis or thrombophlebitis is found to be the etiologic factor, adequate therapeutic measures should be instituted prior to surgical attack on the abdominal tumor.

In patients with suppurative pelvic thrombophlebitis failing to respond to conservative measures and especially those in whom infection has occurred surgical therapy should be instituted. If surgical therapy is undertaken the return flow of the blood from the uterus should be ligated, i.e., the vena cava and both ovarian veins should be ligated. This ligation will save a number of lives and the complications (if any) following this procedure are slight. Following ligation of the vena cava, the risk of postoperative complications may be minimized if the patient is given routine postoperative lumbar sympathectomy blocks or if the sympathetic lumbar chain is interrupted at the time of operation.

JOHN R. WOLFF, M.D.

Burns E. and Butt A. J.: The Significance of Chronic Urethritis in Women. *South Surgeon* 1946 13 352

An analysis of 100 cases of chronic urethritis in women is presented. Carelessness in vulvar hygiene, endocervicitis, pyelonephritis, radium application, sexual trauma, catheterization and the presence of a rudimentary prostate and the presence of a predisposing factor are as described by Folsom may be predisposing factors.

The chief symptoms are those of bladder irritation and pain. The mucosa of the posterior third of the urethra and the vesical trigone present an irregular, red granular appearance. Congestion of the blood vessels, small cysts and inflammatory polyps may be present. The urinalysis generally yields negative findings.

The disease can be cured within 6 or 8 weeks by irrigation of the bladder, dilatation of the urethra with sounds, and the instillation of silver nitrate solutions into the posterior urethra.

GEORGE BLINKER, M.D.

Kolier R.: Appendicitis and Sterility (Appendicitis et sterilitas) *Riv. fr. gyn. obst.* 1946 41 261

It is not uncommon during gynecological operations to see the effects of an old heretofore unsuspected case of appendicitis. In thoroughly reviewing the patient's history a syndrome can sometimes be elicited which in retrospect can be considered an appendicitis with a clinical course which has been in

sidious. Then at the level of the internal genital organs one can notice the presence of adhesions, especially in the right side of the pelvis.

It is not surprising that acute appendicitis, particularly the perforated type requiring drainage can produce adhesions in the immediate vicinity especially at the level of the uterine tubes. The same local reactions can also take place following an attack of appendicitis that has occurred prior to the marriage state and which has given but very mild symptoms.

Various parts of the internal female genitalia may participate in the process of appendicitis but the lesions involving the tubes themselves are particularly liable to impair their function and have the most detrimental effects on fecundation. The uterus and the ovaries may also be involved and be the seat of changes so important that they may constitute the only cause of sterility. Sometimes the sterility is the result of various influences which differ in their degree of participation.

In order that fertilization can take place one of the essential factors is the patency of at least one of the tubes and it is precisely the patency of the tubes that may be impaired following appendicitis. The presence of adhesions can either produce a kink in the tube or exert a pressure on its outer surface. In both instances, the final result is the same—partial or total obliteration of the lumen of the tube. It is understandable that such adhesions can take place following an appendectomy for a severe form of acute appendicitis, especially if drainage has been instituted. Nevertheless, the formation of adhesions should not always be attributed to the establishment of drainage. It may follow any acute inflammatory process which has healed spontaneously without operation.

The adhesions may develop at the abdominal orifice of the tube which may become partially or totally closed. These adhesions may subside disappear and leave a patent tube. Nevertheless, following such an inflammatory process, the tubal wall will lose some of its contractile power which interferes with the progression of the fertilized egg toward the uterine cavity. In these instances, salpingography reveals the perfect patency of the tubes and yet the woman is sterile.

It is not exceptional for the appendicular infection to reach the lumen of the tube where it produces the known effects of endosalpingitis, which finally leads to the welding of the mucosal folds and sometimes to complete obliteration of the lumen of the tubes with the formation of blind recesses, true traps in which the fertilized egg can be immobilized.

A certain number of tubal pregnancies must be found in those anatomical disorders of the lumen of the tube secondary to a colibacillary infection, the primary focus of which is the appendix.

Needless to say the closer the appendix is to the tubes, the more often one will see the dissemination of the appendicular infection to the tubes.

The infection spreads from the appendix to the tube either by direct continuity or through the lymphatics.

Direct contamination is almost fatal when the tube is very close to the infected appendix. It occurs early after the manifestation of the infection in the appendix. Infection by way of the lymphatics may occur late. The latter mode of spread explains why the salpingitis following the appendicitis is sometimes bilateral. On the other hand, the infection may spread from the right to the left side through the uterine mucosa.

Often the ovaries are involved by the infectious process originating in the appendix. The hyperemia associated with the infection produces a permanent congestion of the ovary and finally a sclerocystic oophoritis. Oligomenorrhea and even amenorrhea have been reported to occur following appendicitis.

Appendicitis rarely exerts a direct influence on the uterus as far as sterility is concerned. A retroverted uterus fixed in the pelvis by adhesions is often the cause of sterility.

The charts of 113 patients admitted to the hospital for sterility between 1935 and 1945 were reviewed. 104 or 91 per cent, were classified as having primary sterility and 9, or 9 per cent, as having secondary sterility.

Among these 113 patients, 113 were sterile without having had appendicitis and 90 or 48 per cent, had had appendicitis. In 58 instances it consisted of a simple acute appendicitis which was operated on early under satisfactory conditions without post-operative complications. In 38 instances it consisted of a severe acute appendicitis with peritonitis requiring drainage.

Only 3 of these 90 women underwent appendectomy in childhood. Thus it seems that the appendix exerts greater influence on the genital organs of the adult than on those of the child.

If the existence of an old appendicitis can be detected in the history of these 90 sterile women, one is not yet justified in concluding that the appendicitis is the cause of the sterility. In fact, after a careful study of the charts of these 90 patients, it was found that in only 34 patients could the appendicitis be incriminated as the cause of the sterility. Of the 34, 23 had had simple appendicitis and 19 had had a severe, complicated type.

In 56 patients the appendicitis was considered as a coexisting condition and not as the cause of the sterility.

From these studies, the incidence of sterility following appendicitis is 16 per cent.

GERARD GUYON, M.D.

Mittace F: Hemoperitonism from Ectopic Chorionepithelioma (Emperionoma da corioepithelioma ectopico). *CH. stud.*, 1946, 45, 80.

The author reports the case of a young woman of 25 years a primipara, who spontaneously delivered a vesicular mole in the fourth month of pregnancy without having had the usual clinical symptoms of this condition. The puerperium was uneventful. However during the next 15 months she had a series of hemorrhages at varying intervals without any

great impairment of her general condition. Surgical exploration did not show any tumor of the uterus or ovaries. The Friedmann reaction was definitely but not intensely positive during the whole course of the illness. Suddenly at the end of that period she had a copious retroperitoneal hemorrhage with infiltration of the retroperitoneal tissues from the left iliac fossa to the kidney bed on that side. Postmortem examination showed a small tumor on the sacroiliac wing situated near the bifurcation of the common iliac artery.

There was some question as to whether this tumor was a sarcoma or a chorioepithelioma, but after careful weighing of the evidence the author decided in favor of the latter. The confusion is not surprising as there is a close relationship between these two forms of tumor. There were nodules in the lung which the author believes were metastases, although the histological evidence was not absolutely conclusive.

The only possible method of treatment in cases of primary ectopic chorioepithelioma of which the site cannot be discovered is medical, the disintegrated chorionic villi being prepared by the method of Sivor and Rebaudi. This method of treatment was first used successfully in 1937.

AUDREY G. MORGAN, M.D.

De Giorgi L.: The Relation of Tumors of the Small Bowel to the Genital Organs in the Female (I tumori del tenue nel rapporti con gli organi della sfera genitale femminile). *Arch. ostet. gine.* 1943 6: 27.

The author reports a case of leiomyoma of the ileum with multiple secondary nodules in which the sarcomatoid structure and cellular polymorphism confirmed the clinical impression of malignancy. Although relatively undifferentiated myoblasts were found, it is suggested that the genetic interpretation be evaded and the tumor be defined as an 'atypical' immature leiomyoma, a term which indicates the degree of differentiation as well as the cytological character of the neoplasm. This choice of term arises from the fact that although the degree of dedifferentiation is often directly related to the degree of malignancy, a high grade of malignancy is sometimes found to be associated with a rather strictly adult type of cell and in certain other cases the tumor clearly stems not from the myoblastic but from the mesenchymal elements.

In the case reported, a history of irregular menses, frequent and painful urination, a low grade elevation of temperature, and a tumor mass in the right iliac fossa led to a discussion of the differential diagnosis between tumors of the pelvis and those of the small bowel.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Joseph H., and Hirsch E. F.: Eclampsia. Report of a Case in Which There Was Extensive Destruction of the Brain. *Arch Path Chk* 1946 42 391

The authors describe the pathological changes occurring in the brain of a woman who died 3 months after having eclamptic seizures. There is the literature only one other recorded description of the brain of a patient who survived eclamptic seizures for any essential period, that of the brain of a woman dying 7 years after her illness, which showed widespread cortical degeneration and centrum ovale change. This was reported by Lowenberg and Lowman in 1941.

The patient was a 35-year-old primigravida who had had a mild albuminuria and elevation of blood pressure beginning at the eighth month and had experienced generalized convulsions almost continually during induced labor and delivery. Sodium amytal general anesthesia was successful in eventually controlling the convulsions. However, there was a sharp fall in blood pressure at the time of delivery and oxygen was necessary. The patient never regained mental consciousness and died a few days later at 3 months. On the level of consciousness lay generalized tonic-clonic convulsions. At autopsy the patient was found to be in the postpartum period, and a gradual rise in cerebral spinal fluid pressure was noted.

Essential of the gross anatomical diagnosis at autopsy were a marked encephalomalacia and atrophy of the cortex of the brain. The nonneuropathological findings were consistent with chronic illness. The brain with the upper half of the dura weighed 900 gm. The pinal half was abundant clear and colorless. The pia-arachnoid at the base of the brain was thin and transparent. The arteries at the base had thin walls. The vessels of the cerebellum, pons and brain stem were firm but those of the cerebral hemispheres were soft. The convolutions were atrophic and flattened. The sulci were narrowed. Convolution were isolated with a few thin transparent spots on the parietal and occipital lobes. The dura and the choroid plexuses were not unusual. Microscopically, the brain showed a cerebral cortex 3 mm thick, a narrow layer of loose connective tissue parallel to the pial surface, cerebral cortex pale and friable with white matter. Destruction of the lateral ventricles, normal basal ganglia, cerebellum, pons, and brain stem.

Microscopic examination (staining by van Gieson's method) showed thickened pia-arachnoid, veins dilated with occasional extravasations, poorly stained white matter in the parietal lobe and a third temporal gyrus in contrast to the darkly stained first temporal gyrus. The temporal and parietal cortex focal regions of demyelination in the frontal gyrus, marked cortical destruction in the anterior portion of the cerebral hemispheres with marked loss of nerve cells and fibers and mesenchymal growth along with glial proliferation, coagulation necrosis, cortical capillary and venous dilatation, and mural thickening of dilatation of the perivascular spaces with occasional small hemorrhages. In brief observation showed advanced organization and scarification of cerebral tissue and demyelination of the centrum ovale. Only minimal destructive changes were seen in the cerebellum.

Autopsy reports of brains of women who died during eclamptic seizures have shown in general more diffuse than focal changes. Edema, degeneration of ganglion cells, reaction of glia and meninges, and hemorrhages are the chief findings, all representing on a small scale what was observed by the authors in the form of diffuse damage. All circulation disturbances in the brain are generally thought to be functional rather than actually organic.

Whereas Lowenberg and Lowman assumed that the initial process in the genesis of the disease was necrosis of the nervous parenchyma caused either by functional circulatory disturbances or toxicity, the authors believe that a vascular general rather than a primary parenchymal degeneration is present. Swollen nuclei in cortex and white matter point to a disturbance in blood supply, as does glial proliferation without mesenchymal involvement and also the enormous dilatation of capillaries and small veins adjacent to nerve changes.

In conclusion the authors state that vasoparalysis as well as venous and capillary thrombosis is responsible for most of the lesions observed by them. Anoxemia may be a secondary factor producing the diffuse demyelination observed in the region of the centrum ovale.

The authors conclude that probably central nervous system damage occurs following eclampsia more often than has been reported. Occasional references have been found to psychoses persisting after eclampsia but no systematic neuropsychiatric examination in such patient has ever been done.

Dr. J. B. Cr. et al.

Will G. Rupture of the Capsule in the Eclamptic Liver (Report of a Case in Which the Liver Ruptured). *Am J Path* 1946 52 13

Rupture of the liver is generally brought about by external violence, but in a few cases it may be caused in some cases by toxemia such as in pregnancy toxemia, malaria, typhoid fever and tuberculous peritonitis.

A case of this type of rupture is described in a woman of 32 in the sixth month of her eighth pregnancy. The night before her admission to the hospital she had intense epigastric pain as her blood pressure was very high the attending physician sent her to the hospital the next morning with a diagnosis of high blood pressure from pregnancy. She presented anuria but no convulsions.

Soon after admission to the maternity hospital she collapsed. Her blood pressure fell to a very low level. She was given antitoxic serum and a blood transfusion. A diagnosis of rupture of the uterus was made and operation decided upon. On operation a large amount of blood was found in the abdominal cavity but the uterus was intact. The meson was enlarged upward and an enormous hematoma of the liver 5 cm. in height, was found. The capsule had ruptured and the blood poured into the abdominal cavity. As ligation was impossible a Mikulicz tampon was applied and the abdomen closed. The patient died a few hours later without having regained consciousness.

Autopsy confirmed the presence of a subcapsular hematoma over the whole upper surface of the right lobe. The capsule was ruptured. The liver parenchyma showed multiple recent focal hemorrhages and fatty degeneration. Histological examination revealed complete disintegration of the liver cells. There was also marked parenchymatous degeneration of the kidney cells.

The toxins of eclampsia may therefore have practically the same effect on the liver as external violence.

AUDREY G. MORGAN M.D.

Rochat, R. L.: The Etiology of Spontaneous Abortion—Excepting Syphilis (Étiologie de l'avortement spontané—en dehors de la syphilis) *Gyn. Föld. Par.*, 1946 45 299

This article gives a general report of our present knowledge regarding spontaneous abortion. Although in about 40 per cent of the cases of spontaneous abortion no definite cause can be established modern research in histopathology, biochemistry, endocrinology, serology and genetics has cast new light on the problem.

The belief that syphilis is the most frequent cause of abortion is erroneous. According to French, Italian, and Swiss statistics, not more than 2 per cent of abortions observed in hospitals are due to syphilis. The other etiologic factors can be classified according to whether the etiologic defect lies in the gametes in an anomaly of the ovum and its adnexa or in some general or local deficiency of the maternal organism. Factors which may cause weakness or defects of the sperm or ovum include old age, overexertion (sexual, physical or intellectual), intoxications, infections or unknown constitutional conditions (incompatibility of the partners).

Since according to Williams in abortions of the first trimester the death of the fetus almost always precedes the abortion it is essential for the solution of the problem to find the cause for the death of the

embryo. As a matter of fact, malformations of the embryo and anomalies of the placenta play an important role. In a series of 1,000 abortions, Hertig found abnormal ova in 48 per cent, localized fetal malformations in 3.2 per cent, and anomalies of the placenta in 9.6 per cent. Among the anomalies of the placenta hydatidiform degeneration was the most frequent, arteritis obliterans of the villous vessels was seen frequently also. Furthermore acute hydatidiosis often seems to be the cause of abortion.

Acute or chronic infectious diseases may be transmitted from the mother and cause death of the fetus. According to De Lee certain contagious diseases like scarlet fever and variola may be transmitted to the fetus although the mother does not show any signs of infection. Also of great interest is the question whether focal infections of the mother (teeth, tonsils) may be transmitted to the fetus and cause abortion (Curtis).

Pathological conditions of the uterus causing abortion include endometritis, fibroids (especially the submucous form), retroflexion and hypoplasia whereas malformations seem of minor importance.

Diseases and deficiencies of the mother that may lead to abortion are acute infections like typhoid, smallpox and measles, by way of fetal infection in toxemia or hyperpyrexia. Of the chronic diseases the various forms of nephropathies have been discussed the most. It seems, however, that only chronic hypertensive nephritis plays a certain role in repeated abortion. This occurs mostly in the second trimester and is usually caused by placental hemorrhages.

That diabetes has a most unfortunate influence on pregnancy is a well known fact. Before the insulin era, from 60 to 80 per cent of the cases resulted in abortion. Under insulin therapy the percentage of abortion still is 25 per cent (White). The cause of the interruption seems to be acidosis.

Cardiac conditions seem to play a minor role, if any. The author reports in detail modern researches concerning vitamin deficiency as the cause of abortion. According to Rosemann the vitamin C content of the placenta increases progressively during normal pregnancy whereas the content in the circulating blood decreases proportionally. At the time of spontaneous abortion the vitamin C in the placenta drops rapidly. Most probably ascorbic acid is essential for the formation of progesterone in the corpus luteum. The need of vitamin C is tripled during pregnancy (from 70 to 100 mgm.). However the author asks the following question: If the role of vitamin C is really very essential in pregnancy how can it be explained that the percentage of abortions and premature deliveries in the European countries did not increase during the war in view of the very low supply of vitamin C?

As to the influence of vitamin E a striking discrepancy exists between the experimental and clinical experiences. Rats fed with food deficient in vitamin E aborted on the thirteenth day of pregnancy, but this abortion could always be prevented by a

supply of vitamin E, natural or synthetic (tocopherol). The clinical experiences were not equally satisfactory. Whereas some authors published very encouraging results, others did not have any success. This apparent contradiction is easily explained if the vitamin E content of the blood is examined in every case. Success of vitamin E therapy can be expected only in cases of vitamin E deficiency. The vitamin E content of the blood should be above 400 gamma per cent (the average is 678 gamma per cent). All cases with a content below 400 should be subjected to treatment, and in these success is obtained in almost 100 per cent.

Among the various hormonal deficiencies, that of progesterone plays the most important role in habitual abortion. In normal pregnancy the amount of progesterone in the urine increases between the seventh and nineteenth days. This increase is not observed in habitual abortion. Browne and his collaborators believe that in these cases there is a gap between the cessation of corpus luteum function and the beginning of intraplacental secretion. Many cases of failure following progesterone treatment may be due to insufficient frequency of the injections. Since progesterone is eliminated quickly, it should be given in a preparation of low resorption (Intocyc line) and continued for a long time. However, this treatment may lead to missed abortion if it is started after the death of the embryo.

As to estrogenic hormone deficiency as well as excess secretion has been believed to be the cause of abortion. Insufficient secretion may lead to hypoplasia of the endometrium (infantilism) which endangers nidation.

The role of the anterior pituitary lobe is still undecided. However, experiments seem to indicate that its normal functioning is essential for the continuation of gestation. Whether hypothyroidism predisposes to habitual abortion, as some men believe, appears doubtful. In a series of 501 cases, the author did not observe a single case of hypothyroidism.

No definite evidence has been found pertaining to the Rh factor as a cause of habitual abortion.

It appears rational that the mechanism of immunization may present a new etiological element in habitual abortion, but the observations are still too incomplete to form a definite opinion. The influence of lethal genes may also have a bearing on habitual abortion. Although experiments on mice have proved definitely that the lethal gene is a fact, nothing is known as yet about its action in man.

WALTER M. SOLMITZ, M.D.

LABOR AND ITS COMPLICATIONS

Da Cunha, D. P.: Abdominal Cesarean Section (Cesaria) (Lithuania). *Rev. de St. Maternal* 104.

The author reviews the history of cesarean section and describes the details of various forms of the operation. He then discusses 168 cases which he has treated—15 by high or lateral cesarean section, 20

by low section, 7 by the Portes operation and 17 by cesarean operation accompanied or followed by hysterectomy. He believes that the low operation is to be preferred to the high one as being less dangerous to both the mother and child. The lower segment of the uterine wall is much thinner than the upper one and does not contract during labor. The author's low operation is transperitoneal while that of Portes is extraperitoneal. There was a total of 83.3 per cent of the author's cases. The fetal mortality was 3.0 per cent. The total maternal mortality for the whole group was 5.05 per cent. Subtracting 3 cases in which the patients died from the anesthesia and one case of death due to brain failure 18 days after the operation, the real operative mortality was 4.1 per cent. The mortality in the low operation was 3.3 per cent and in the high operation on 13.5 per cent. There were complications in 20 per cent of the cases, which incidence is lower than usual. Siegel reports from 36 to 58 per cent, and Fau report 20 per cent of very severe complications.

ANDREY C. MORCA, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Greenberg, E. M.: The Fourth Stage of Labor (in J. Obst. 1914, 52-745).

The sequence of intrauterine event which transpires during the postplacental hour comprises a distinct physiological and clinical entity. Their collective recognition as the fourth stage of labor would help save the lives of those mothers who die of unhealed postplacental hemorrhage and spare the survivors the complications of sepsis and anemia that lie in its wake.

As the sulfonamides and antibiotics seal the doors of puerperal infection, puerperal hemorrhage will eventually take first place among the causes of maternal mortality and as the attempt to combat puerperal hemorrhage gain in momentum, the critical first postplacental hour will necessarily have to be accepted as a normal part of every labor for as a series of individual but interrelated physiological components, the fourth stage of labor will have to be recognized and treated with understanding, lest one of its component rebel under maltreatment and cause destruction.

The physiology of the fourth stage of labor consists of a contractile and a hemorrhagic phase. The contractile phase includes the stages of (a) "uterine myotomponade" or immediate uterine contraction, (b) uterine thrombotomponade or secondary relaxation with the formation of placental sequestrations and intrauterine hematomata, (c) myotensive indifference, and (d) fixed myotensive contraction. The hemorrhagic phase includes traumatic hemorrhage from vaginal tract bleed, secondary antepartum hemorrhage with a clotting hemorrhagic component associated with placental separation and a nonclotting hemorrhagic component probably arising from denuded myometrium. Both the contractile and hemorrhagic phases are multicausal and inter-

related. The normal nonclotting component of postpartum blood may be analogous with the nonclotting component of menstrual blood which this author believes also consists of two components—a clotting and a nonclotting. The same uterine enzyme which may be responsible for the failure of one of the postpartum blood components to clot may be responsible for the failure of one of the menstrual components to clot. Postpartum hemorrhage when not due to uterovaginal tract trauma, may consist of a hemorrhage of (a) one of the clotting components (b) the nonclotting component or (c) a combination of any two or all three. Shock bleeding may be a superimposed late complication.

The official recognition and physiological appreciation of the fourth stage of labor would result in a reduction of mortality from postpartum hemorrhage, which is assuming first place among the causes of maternal mortality. A questionnaire concerning the fourth stage of labor should be a part of every labor record.

JOHN R. WOLFF, M.D.

NEWBORN

Page E. W. Hunt, M. and Lucia, S. P.: The Antepartum Prediction of Hemolytic Disease of the Newborn. *Am J Obst* 1946 52: 794.

Despite the intensive researches on the relationship of erythroblastosis fetalis to the Rh factor, the obstetrician is handicapped because he is unable to forecast the outcome of pregnancy in Rh negative women. Not only is he in doubt about the presence

or absence of erythroblastosis fetalis in utero but he is also unable to predict its gravity when there are reasonable clinical indications that it may exist.

Ideally all pregnant women should be typed routinely regardless of parity and in those Rh negative patients having Rh positive husbands the first sample of blood for antibody determination should be obtained not later than the twenty fourth week of pregnancy. If this be strongly positive for either agglutinating or blocking antibodies an Rh positive fetus will probably be too seriously affected by hemolytic disease to warrant any interference before term while an Rh negative fetus will escape the disease. As yet there is no way of distinguishing these possibilities except to prove that the father is homozygous for the Rh factor. If the antibodies are present only in traces or if a small amount is found on a single determination and is unconfirmed by subsequent tests the fetus is probably unaffected and again it would be unwise to interfere.

If the initial sample is free of antibodies but a significant amount appears later a period of 8 to 10 weeks may be allowed to pass before hemolytic disease becomes a probability. After this time induction of labor might be warranted provided the expected date of confinement is within the ensuing 6 weeks.

That a relationship exists between the duration of exposure to maternal antibodies and the fetal prognosis seems apparent. Further study may alter the critical time periods established by the data of this preliminary analysis.

JOHN R. WOLFF, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Wagner, F. H. Jr.: Arteriography in Renal Diagnosis. *J. Urol. Balt.*, 94b:56-63.

Röntgenological delineation of the abdominal aorta and its branches in humans following direct translumbar injection of a radiopaque medium attracted considerable attention but its seemingly formidable nature prevented general adoption. Although the technique is exacting the indications limited and the films some times difficult to interpret the encouraging reports warrant its further trial in properly selected cases by qualified personnel.

The purpose of the present article is to stimulate further interest in this subject by the description of a simplified technique, critical evaluation of the procedure and the presentation of some unusual arteriograms.

A team consisting of a surgeon, an x-ray technician and an anesthesiologist is required.

The necessary equipment: an anesthetic solution gauze squares, drapes, rubber gloves, normal saline solution, talcum powder, rubber tubing with Luer lock adapters, a 15 cm. No. 18 gauge needle with side skin puncture needle, a 10 c.c. Luer lock syringe, 80 per cent sodium iodide.

The x-ray machine should be capable of delivering 500 milliamperes. A high speed (ucky) diaphragm should be used, all wing exposure with one fourth of a second.

The anesthesiologist should be provided with pentothal anesthesia equipment and an x-ray machine. The preliminary preparations are as follows:

1. On the day of the procedure a soapud enema is administered to the patient in the morning and (solid) withheld.

2. Morphine and atropine preanesthetic medication is given three-quarters of an hour before the procedure.

3. The sterilized arteriography tray, the pentothal anesthesia equipment, an intravenous set, 1000 c.c. of 5 per cent glucose in normal saline solution, a syringe containing 1 c.c. of epinephrine solution (1:1000) and another syringe containing 15 c.c. of cocaine are sent to the examination room with the patient.

4. With the patient in the supine position, an abdominal film is taken in order to note adequacy of the colon preparation, to determine the best centering of the film with respect to the area of diagnostic interest and to check the x-ray technique.

5. When the film is satisfactory or after necessary corrections have been made the cassette is again loaded and the patient is anesthetized lightly with sodium pentothal.

6. The skin of the lower chest and back prepared with antiseptic solution and draped.

The technique of object is as follows:

The twelfth rib on the left side is palpated. With a short stout needle the skin is punctured just below this rib 4 fingers breadth from the spinous process. The 15 cm. needle is then introduced through the puncture hole and directed anteriorly medially and cephalically toward the body of the twelfth thoracic vertebra. When bone is encountered, the needle is withdrawn about 2 cm. and the point is directed more laterally so as just to pass by the vertebral body. The stylet is then removed and the needle cautiously advanced to within a few centimeters of its hub. The aortic wall is encountered as a resistance through which the needle snaps, imparting to the operator a sensation similar to that experienced in penetrating the dura mater during a spinal tap. Almost immediately bright red blood emerges from the needle as a pulsating drip which descends as a rivulet on the skin. To patients with hypertension the flow more rapid and pulsation somewhat more vigorous but the amount of blood lost in making the necessary adjustments for injection is trivial. In some instances the needle itself may be seen to move rhythmically with each heart beat.

The needle is then connected to the rubber tubing and syringe which have been previously filled with sterile saline solution. Barbotage is carried out, note the ease of flow in both directions. A trial injection of 10 c.c. of saline solution within 6 seconds is made in order to estimate the force required. The stopcock is then closed, and the syringe is disconnected and filled with approximately 10 c.c. of 80 per cent sodium iodide solution.

The syringe is again connected, the stopcock opened, and blood withdrawn as a final proof that the needle is well within the lumen. The signal "ready" is given to the x-ray technician, the solution is injected at a rate of 2 c.c. per second and the signal "shoot" is given as the final cubic centimeter or two leave the syringe. Since the tubing holds about 2 c.c., the total amount delivered to the aorta is about 10 c.c. Immediately following exposure of the roentgen film the needle is withdrawn.

It has been the author's experience that the technique as just described is best suited for visualization of branches of the celiac axis and superior mesenteric artery. Visualization of the renal artery and its branches appears to be better if the needle is inserted one vertebral level lower.

Promptly after injection, the patient usually moves slightly and breathes more deeply. During this period oxygen is administered by the anesthesiologist and careful watch kept of the patient's color, respirations, and pulse. The needle through which the pentothal was given is left in place and used for the administration of 1000 c.c. of 5 per cent glucose in normal saline solution. Within 10 minutes the patient usually becomes conscious and has no complaints. Several hours later the patient is allowed his regular tray.

ambulation is permitted if there are no other contraindications.

The author states that before abdominal arteriography is undertaken one should be fully acquainted with the difficulties and potential dangers. In the first place the patient is exposed to the hazards of anesthesia, acute iodism, extravasation of radiopaque medium, and hematoma following puncture. Secondly the operator must acquire a thorough knowledge of the relational anatomy involved in the procedure. Aortic puncture should first be practiced in the dissecting or postmortem room in order to acquire experience and confidence. Thirdly the actual technique, though relatively simple is exacting and demands perfect co-ordination of the team for the slightest error may yield an unsatisfactory film. Finally even an excellent arteriogram in some instances may be difficult to interpret accurately because of the present lack of experience.

Even if the risk of abdominal arteriography in the hands of a competent team is granted to be minimal the question arises as to whether sufficiently valuable information is obtained by the procedure to justify its performance. It is my opinion that this study is of value, just as arteriography elsewhere in the body as an occasional diagnostic adjunct in carefully selected instances. From the standpoint of renal diagnosis the study may be indicated when all other studies have been exhausted and further information is desired regarding (1) hypertension in which surgical treatment is contemplated (2) aberrant renal vessel as a possible cause of hydronephrosis, (3) renal or adrenal tumors (4) possible renal aneurysm and (5) suspected aortic obstruction near the renal arteries.

Further investigation and pooling of information with respect to interpretation of the arteriograms will, no doubt, establish the normal range of variation as well as the abnormal patterns. A rotating cassette, permitting multiple exposures during injection of the radiopaque medium, would afford a more certain method of obtaining a good film during maximal concentration of the material in the area of diagnostic interest. Stereoscopic films would permit even more precise arteriographic delineation. Finally in the near future cinerentgenography and the fluorographic multiple exposure technique may be successfully incorporated into the method.

JOHN A. LOEF, M.D.

Abeshouse B. S., and Tankin L. H.: Renal Complications of Sulfonamide Therapy. *J. Urol.* Balt., 1946 56 658.

The authors discuss the following renal complications of therapy with sulfanilamide, sulfapyridine, sulfathiazole, sulfadiazine and sulfamerazine: (a) crystalluria (b) hematuria (c) oliguria and anuria, (d) renal or abdominal pain or colic, (e) tenderness over the kidneys, and (f) azotemia.

Clinical reports of renal complications of sulfanilamide are rare. The authors have observed an unusual case of anuria following the intraperitoneal injection of from 75 to 85 gm. of sulfanilamide. Complete

anuria occurred but an autopsy was refused and the exact nature of the renal changes could not be ascertained.

In their series of renal complications of sulfapyridine hematuria was observed in every one of the 12 cases and was accompanied by renal colic in 2 cases and by urolithiasis, azotemia and anuria in 1 case each respectively. Cystoscopy was not done in any case. There were no fatalities.

In the authors' series of 12 cases of renal complications following sulfathiazole therapy there were 7 cases of hematuria (3 cases uncomplicated, 1 with azotemia, 1 with crystalluria, 1 with oliguria, and 1 with anuria), 2 cases of crystalluria, and 3 cases of anuria. Cystoscopy and ureteral catheterization were employed in 3 cases. There were no deaths in this series.

Fourteen cases of renal complications of sulfadiazine are reported. Hematuria was encountered in 10 cases (2 cases uncomplicated, 4 with renal colic and azotemia, 1 with crystalluria, 1 with renal stone, 1 with oliguria, and 1 with anuria), oliguria and azotemia in 1 case, anuria in 1 case, and crystalluria in 2 cases. There was 1 death in this series. The death was preceded by anuria and at autopsy thrombosis of both main renal arteries was found.

The authors observed only 2 cases of anuria following sulfamerazine. 1 was accompanied by hematuria and 1 by renal pain. One of them was successfully treated by ureteral catheterization and the other responded to conservative therapy.

Certain diagnostic aids are suggested. A daily urinalysis may allow detection of microscopic hematuria, one of the earliest signs of renal change. The presence of crystals in the urine without other signs or symptoms does not necessarily mean renal damage. Urinary infections predispose to the development of renal or ureteral complications. Obstructive lesions in the upper or lower urinary tract favor the accumulation of crystals or the formation of uroliths within the obstructed area.

Cystoscopy and ureteral catheterization usually establish the diagnosis.

The following precautions will reduce the incidence of renal complications: (1) determination of previous sulfonamide medication, sensitivity or idiosyncrasy, (2) evaluation of the state of renal function prior to the administration of the drug, (3) evaluation of the state of hydration, (4) administration of the drug in adequate dosage, and (5) administration of adjuvant alkali therapy.

It is believed by the authors that the drug should be stopped immediately upon discernment of evidence of kidney damage, i.e., hematuria, renal pain or tenderness, suppression of the urine and increased nitrogen retention. The fluid intake should be increased and solutions of hypertonic dextrose and isotonic sodium lactate given intravenously. Sodium bicarbonate should be given by mouth until the carbon dioxide combining power of the blood reaches between 70 and 90 per cent. However there is a warning against giving excessive amounts of fluids.

The use of mercuric compound is and acid diuretic is absolutely contraindicated. Ureteral catheterization and pelvic lavages with warm water isotonic saline solution or from 2.5 to 10 per cent sodium bicarbonate solution are indicated when the pelvis or ureters are obstructed by sulfamide crystal. When all these measures fail nephrostomy pyelotomy or ureteropyelostomy with or without renal decapsulation have proved to be lifesaving in otherwise hopeless cases.

The cases reported by the authors were from the Sinai Hospital Baltimore Maryland
JOSEPH L. ALLEN, M.D.

Lundström, E.: A Belt for Compression of the Ureters (Cuert för Kmpression der Ureteren). *Läk. Med. Stockholm* 1946 27 385

Compression of the abdomen with the purpose of preventing the escape of contrast material into the urinary bladder is used for intravenous as well as retrograde pyelograms. The usual compression band which is attached to either side of the roentgen table causes pain to the patient whose back is pressed against the table. Furthermore it immobilizes the patient and makes multipositional (especially oblique) roentgenography impossible.

The author describes an improved compression belt the description of his first belt having been published in 1937. The present belt consists of an abdominal and a dorsal shield of radiotranslucent material connected by straps. Rubber balloons of varying sizes (for unilateral or bilateral ureteral compression) can be inserted underneath the front piece and inflated to from 40 to 80 mm. Hg by means of a hand pump with a manometer.

The patient can be moved freely while the compression is being maintained. On the other hand release of the compression can be accomplished by

Fig. (Lundström)

removing the front piece of the belt without disturbing the patient's position.

BLADDER, URETHRA, AND PENIS

Emmett, J. L.: Management of Cord Bladder by Transurethral Resection. *J. Urol. Balt.* 1941 57 20.

The author analyzes 45 cases of cord bladder caused by transurethral resection at the Mayo Clinic during the years of 1941 and 1943. Thirty patients had transverse lesions of the cord and 13 had diffuse lesions. All of the patients carried a residual ranging from 50 to 1,200 c.c. The pattern of vesical dysfunction varied greatly but consisted for the most part of involuntary active emissions of varying amounts of urine at intervals of from a few minutes to an hour or more. This type of vesical dysfunction has been termed the automatic or reflex bladder. Most of the patients were reconciled to their partial motor paralysis but complained bitterly of a severe urgency of micturition which made the wearing of some type of urinal necessary.

Transurethral resection as carried out in these cases has as its object the destruction of the internal sphincter's capacity to contract and the removal of any obstructing tissue so that there will be no resistance of any kind between the bladder and the external sphincter. To do this, the entire circumference of the vesical neck, well out to the verumontanum, must be resected. Multiple resections are frequently necessary before the patient can empty completely.

The results in 30 cases of transverse myelitis were encouraging. Twenty-three patients were considered to have obtained a good result, 4 were improved in 2 patients the results were fair and in 1 patient, poor.

Fifteen patients with multiple sclerotic or miscellaneous lesions of the cord, were studied. Usually these patients were found to have frequency and urgency of micturition with a poor stream. In all "mild" cases the patients complained of a prepotent urgency. Three of 7 such patients obtained a good result; in the remaining 4, the results were classified as fair.

It is emphasized that the performance of resection by no means treats the neurological lesion. In the final analysis the attempt with this procedure is to eliminate residual urine so as to allow the patient to remain dry until an amount equal to that of residual urine accumulates in the bladder. This accomplished, he may be kept dry and free from cumbersome catheters and urinals, thus greatly aiding his entire program of rehabilitation.

Excellent charts analyzing each of the cases are presented.
ROBERT O. BLUMBERG, M.D.

Lewis, E. L.: Tuberculosis of the Penis. *J. Urol. Balt.* 1945 56 737

Tuberculosis of the penis is a rare clinical entity. Two types have been recognized: (1) that which is secondary to other lesions in the genitourinary system.

(a) upper tract, (b) genital tract and (c) both and (3) that which is primary i. e. no other source of tuberculosis in the body is present. There have been only 3 cases reported in which the penis became involved following pulmonary tuberculosis without there being some other genitourinary focus first.

Tubercle bacilli may involve the skin the urethra or cavernous bodies. Tuberculous cavernitis is a very rare disease and is not considered in the present study except where it may arise secondarily to skin tuberculosis.

The urethral mucosa is remarkably resistant to the tubercle bacilli, which may pass through it for years without producing clinically recognizable lesions (Young). Even so tuberculosis of the urethra is a more common disease than that of the penis: it was present in 2.6 per cent of the cases of upper tract tuberculosis in the author's files, whereas penile tuberculosis was present in just less than 1 per cent of cases.

In a comprehensive review of the literature there have been found 110 cases of penile tuberculosis. In 89 of these the condition was primary in 9 cases, not stated in 8 secondary in 5 cases, undetermined and in 3 cases, hematogenous.

Of the 89 cases of primary tuberculosis 72 were the result of ritual circumcision in Jewish infants. The actual incidence of tuberculosis of the penis following this rite was much higher than a review of the literature would indicate. Part of the ritual consisted of the mohel sucking the circumcised penis in the act of the *Melizah*. The purpose of this act which was compulsory as described in the Camera by Rev. Rav Pope in the fifth century and later by Joseph Karo and Maimonide in the Beth Joseph of the twelfth century was that of a hemostatic and styptic. Syphilis and diphtheria have also been contracted through this act. After the turn of the last century this act was practically eliminated from the ritual so that tuberculosis of the penis is seen only rarely now.

Of the remaining 17 primary cases, 12 were definitely stated as being the result of coitus, 2 were the result of nonritual circumcision, 2 the result of buccal coitus, and 1 case resulted from the wearing of infected clothing.

Of the secondary cases 4 patients had tuberculosis involving the genital system, 2 had renal involvement and both the urinary tract and genital tract were involved in the other 2 patients.

In the Brady Urological Institute there have been seen 7 cases of tuberculosis of the penis, 5 of which the author reports.

As has been demonstrated, the penis may become infected with the tubercle bacilli through three sources: (1) hematogenous from lungs, (2) direct contact, and (3) following tuberculous infection of other organs in the genitourinary system by one of the above methods or by some other method not demonstrated as yet.

The hematogenous route without involvement of other genitourinary organs is an extreme rarity.

The direct contact source is by far the most common source of infection. One can easily see how the bacilli could gain a foothold during circumcision, but

the contraction of the disease through coitus is another matter. The tubercle bacilli can be found in the vagina in cases of pelvic tuberculosis in women, and even though cervical tuberculosis is a rare disease it has been seen and shown to be of primary as well as secondary origin. This being so and the fact that the lesion appears around the corona and frenulum most commonly leads one to speculate that the bacilli are inoculated in these points of irritation; the normal mucosa having been shown to be highly resistant.

There have been many descriptions in the literature of the typical lesion of tuberculosis of the penis. Brunati describes 3 periods in the development of the tuberculous ulcer. The first period is one of a tuberculous pustule which he calls a 'bouton' or raised pimple. In this stage there is little or no induration. In the second period there is ulceration but still little or no induration. The third period is marked by a progression of the ulceration, and the presence of infiltration and induration around the edges. The base, in the early stages of this period, is usually clean and has the appearance of irregular granulation tissue. With extension of the lesion there is necrosis; the base becomes gray or yellow and usually there is secondary infection.

The differential diagnosis of penile ulcers is not simple. There are many diseases to be considered: *vulva balanitis*, *herpes procerialis*, *chancroid*, *lueitic chancre*, *epithelioma*, *carcinoma*, *gummatous ulceration*, *granuloma inguinale*, and *leprosy*.

Because of its rarity the diagnosis of tuberculosis should not be made until all other possibilities have been ruled out. The diagnostic proof should consist of smears stained for acid fast bacilli, biopsy and finally animal inoculation. In only the last of the cases here presented was all this done.

The treatment of penile tuberculosis has been most unsatisfactory. Suggested therapy has been heat, light (both ultraviolet and infra-red), x-ray, various chemicals and surgical excision. None of these methods has proved to be a panacea. In some cases excision with the electric cautery can be done with some optimism for the patient but the prognosis generally is quite poor.

MISCELLANEOUS

Reaves, J. U: Surgical Injuries of the Urinary Tract
J. Urol. Balt. 1947 57 65

Injuries to the urinary tract are of two types: (1) those which allow urinary absorption without extravasation and (2) those which allow extravasation and absorption. When urinary extravasation is set up the urine follows every conceivable plane, giving unlimited variety to the fistulous tract. The scope of the present paper deals only with those cases which are due to surgical trauma, or to external violence as is sometimes encountered in private practice.

Accurate diagnosis of fistulas following injury to the kidneys can be made as a rule by the properly combined use of urologic and roentgenographic sur-

vey The presence or absence of hematuria is noted, and either intravenous or retrograde pyelograms are made according to the operator's judgment, remembering that temporary anuria can result from either moderate or severe trauma of the kidneys.

Immediately following an injury in which the kidney is involved the patient complains of pain and tenderness in the iliocostal area. The pulse rate is rarely accelerated and the blood pressure will remain at a safe level. Muscle spasm in the area is usually due to the degree of injury to the muscle. Pain, tenderness, and muscle spasm may be accompanied by shock, though shock is rarely severe unless the kidney injury is complicated by injuries to other structures. If the pulse rate is accelerated and accompanied by restlessness and the pain and muscle spasm increases, one may be certain that progressive bleeding is going on. Likewise a fall in blood pressure several hours following injury is often caused by bleeding. In the opinion of the author this should put an end to expectant or conservative treatment, and exploratory surgery should be instituted.

The anatomical position of the ureters, together with elasticity gives them a large degree of protection from injury. The possibility of the ureter being nicked or severed by a gunshot or stab wound is remote though this could happen. If the ureter is injured at the same time the kidney is damaged the kidney disease is dealt with primarily and in so doing the ureter also comes in for attention. This may be simple ligation of the ureter and removal of the distal portion thereof during a nephrectomy or drainage and plastic repair accomplished according to the presenting indications. Sometimes the ureter is injured during resection of the sigmoid for malignant growth rendering a condition which is so aggravating that nephrectomy has to be resorted to.

Injury to the ureter is not always recognized at the time of operation. A fatal peritonitis may result from an unnoticed rent in the urinary tract with the escape of urine into the peritoneal cavity. Complete anuria or the presence of hematuria may reveal ligation or other injury to the ureters. The appearance of urine on the dressings or through the vagina may be the first notice of operative injury.

Newell states that there are no definite symptoms in unilateral ligation of the ureter that the death of the kidney occurs before the ligation is absorbed and in such cases the effect of this ligation may not be observed.

Distortion of the urinary tract by pelvic disease can be ascertained by a preoperative urological survey. This will also show up double ureters, Y ureters and the like and make it easier for the gynecologist to be on the alert to avoid injury to the ureters. Likewise an early urological survey postoperatively will show the degree of damage or malplacement left with the patient following the operative procedure.

Operative injuries to the bladder are more rare than ureteral injuries, as it is extremely difficult to injure the bladder when it is empty and contract

ed however fatal peritonitis may result from an unnoticed rent in the bladder allowing the escape of urine.

One of the most difficult urological problems is that which accompanies or follows posterior resection of the rectum, or combined abdominoperineal resection. The urinary retention and infection must be held to a minimum when this complication is present. The explanation most frequently accepted is that which attributes this complication to injury to the parasympathetic nerves which control the urinary bladder. Just why this urological condition should exist at all has never been adequately explained. Trauma to the prostate, posterior urethra, and seminal vesicles and further disturbing the supporting structures around the base of the bladder during this operation tend to set up a condition wherein the bladder decompenates, and is found unable to expel urine through a moderately obstructed vesical neck. When this condition exists the vesical neck should be weakened by resection, thus obviating the imbalance existing between the vesical neck and the detrusors. This procedure is not to be attempted until enough postoperative time has elapsed for the patient to regain his vesical function.

Hinman classifies rupture of the urethra as being of four types: (1) of the pendulous portion, (2) of the bulbous portion anterior to the triangular ligament, (3) of the bulbomembranous portion anterior to the triangular ligament, and (4) membranoprosthetic portion at or posterior to the triangular ligament. Dodson states that, with few exceptions rupture of the urethra occurs as the result of a direct blow of the perineum forcing the urethra against the pelvic arch, or as the result of fracture of the pelvic bones.

The author has seen 9 cases of fracture of the urethra, followed by extravasation of urine, in which the bladder was filled close to its capacity at the time of injury. It is believed that the weight of bladder urine, and the movability and sudden jerk caused by the traumatizing agent makes a more complete and extensive laceration of the urethral tract. In such cases the patient's attempt at voiding is not met with success, and it is usually accompanied by such severe pain that immediate relief is sought.

If perineal repair of the divided urethra is required, the urinary diversion and urethral repair can be accomplished and the hemorrhage controlled by exposure per perineum. It is not always easy to find the distal ends of the severed urethra in some cases it is necessary to open the bladder suprapubically and to pass a sound posteriorly as well as through the perineal wound, or through the urinary meatus, in order to approximate the severed ends of the urethra. Retrograde instrumentation is always best in these cases. After the ends of the urethra are located the repair is easy. The author uses end-to-end anastomosis and perineal closure after a free resection of all bruised tissue and the traumatized ends of the urethra, together with closing of the bleeding points in the ruptured membranous bulb, if such existed.

JOHN A. LOER M.D.

Deming, C. L. : Drainage and Irrigation of the Urinary Tract. *J Urol* Balt. 1947 57 49.

The modern conception of drainage and irrigation of the urinary tract not only implies relief of obstruction and cleansing of the tract by irrigation but embraces a consideration of the physiology, bacteriology and pathology of the tract as well as the prevention of cardiovascular disease, renal complications and hypertension. To accept the principle that any drainage or any so-called tidal irrigation will function continuously without attention is like expecting that your automobile will run continuously without regular and proper adjustment. The fact that the insertion of a drainage tube into any uninfected bladder or kidney will result in an infection of that organ is not yet universally recognized. Irrigations including the so-called tidal drainage for the bladder do not prevent invasion by bacteria, nor does an irrigation completely sterilize organs lined with mucous membrane, it causes only a mechanical cleansing of the epithelial surface and consequently any irrigation which will cleanse the surface without producing a chemical irritation will be efficacious.

The directives issued by the Army during the last war relative to so-called cord bladder lesions have required suprapubic drainage and indicate recognition of the inadequacy of interval catheterization and tidal drainage. Slow decompression of the distended bladder is now generally conceded unnecessary if precautions are taken against a sudden and serious infection. Likewise it would seem that tidal drainage is doomed or that it will be replaced by less complicated mechanisms. The author has not used the so-called tidal drainage for more than 4 years because of its inadequacy and complexity.

The apparatus for urethral bladder drainage and irrigation which has been used for several years is simple, efficient, economical, and gives little trouble. The author claims no priority with its use. It consists of a three way catheter and flask of irrigation fluid so constructed as to be a closed system. The apparatus used is the ordinary Fenwal flask which contains physiological saline and is the same apparatus as is used for clays and intravenous therapy. The flask always has a ready supply of flasks filled with sterile physiological saline. When one bottle is empty it is just a matter of removing the glass rod from the empty flask and inserting it into the new one always keeping the irrigating fluid sterile and the system a closed one. Patients never complain of flow becoming occluded the inflow usually ceases. If the return fluid becomes cloudy it is a simple matter for the nurse or the doctor to allow the flow to run faster for a minute or two until the return fluid is clear. This can be done at any visit at the bedside. No added apparatus or personnel are necessary to irrigate the bladder adequately. The bladder remains collapsed except now and then and the base is constantly irrigated so that there is very little opportunity for absorption of infection and development of upper urinary tract complications. It is an im-

provement on tidal drainage, even when used for irrigation of the paralytic bladder.

By means of this apparatus preoperative prostatic patients with residual urine are given a continuous saline irrigation by means of a Foley 18F or 20F catheter. Transurethral resection cases are treated and the bleeding is not exaggerated or prolonged. Following suprapubic prostatectomy irrigation is carried out similarly via urethral catheter and suprapubic tube. After 3 to 5 days the suprapubic tube is removed and the wound is allowed to heal. Patients are treated in the same manner following perineal prostatectomy by continuous irrigation through the catheter and perineal tube. After removal of the perineal tube continuous irrigation through the urethral catheter is continued as long as the catheter remains to keep the bladder and the wound clean.

Much has been written about the drainage of the space of Retzius, and many surgeons seem to have been bogged down in this space. Numerous methods of drainage and various kinds of drains have been inserted. Prolonged drainage has produced complications of a permanent fistula and even osteomyelitis of the pubic bones. The author wishes to call attention to the last contribution of the late Henry Morton in which he stressed the fact that when the operator exposes the bladder suprapubically he should incise the pubovesical or prevesical fascia transversely turn it down and thus avoid opening the space of Retzius. If the space of Retzius is not opened it is unnecessary to drain this area in operations on the bladder.

Boyd has shown the advantage of a rubber tissue drain inserted down to the muscular layer at the upper angle of a long incision in a fat abdominal wall or when the wound is severely contaminated by the bladder contents. However due to the advent of sulfa drugs and penicillin this is now rarely necessary. Drainage of the ureter has given some surgeons much concern and as one visits various sections of the country one finds draining ureteral fistulas. It has been our fortune not to have been troubled with ureteral fistulas. It must be remembered that ureteral wounds heal readily if given half a chance provided that there is freedom of flow of urine in the incisions heal well if a closure of the serous layer is done with fine catgut (00000). If the incision is made on the under side or posterior side similar to a posterior pyelotomy wound there is rarely any leakage. In cases in which the ureter is large and the urine is purulent a gall bladder T tube inserted for a couple of weeks has given the most satisfactory drainage. It allows for irrigation of the whole ureter and free drainage, and the wound rarely leaks urine after the T tube has been removed. The T tube is also of advantage in making an anastomosis of an accidentally severed ureter or in segmental resection of the ureter with end to end anastomosis.

The surgical drainages of the kidney are too numerous to describe also the various tubes and

combinations of tubes are many. However the irrigations of the kidney are few and limited mostly to an attempt to dissolve renal calculi with phosphoric acid or the so-called Suby's solution. It is a generally accepted fact that if the kidney is to be drained surgically nephrostomy drainage is preferable to pyelostomy drainage. It is agreed by all that large pyonephrotic kidneys respond better to a large nephrostomy tubular drain passed through the cortex into the pelvis of the kidney and that such drainage shall remain until as much of the restoration of the renal function as possible has been obtained.

The solution of the problem of reconstruction of the kidney pelvis and its drainage in cases of hydronephrosis has been attempted by a number of surgeons, with success by many of them. Two facts are paramount: the first is that if there is an infection the pelvis must be drained; the second is that enough of the hydronephrotic pelvis must be removed to prevent pooling of the urine which often causes a rupture of the suture line and a perirenal infection or recurrent fibrosis at the operative area. After excising the ureteropelvic junction and excess pelvis the anastomosis of the upper ureter is made to the dependent portion of the pelvis over a T tube 12 to 16 F whichever best fits the ureter. It is unnecessary to disturb the renal cortex or drain the kidney with a nephrostomy tube. The T tube acts as a splint and

is removed about the sixteenth day. In only one of the author's cases was there a leakage of urine after removal of the tube and that occurred for only part of a day.

Operations upon the uninfected obstructed kidney now more than ever before are due for more serious reflection. We recognize the fact that hypertension may be due to renal ischemia. Theoretically may not such a lesion however minute be initiated by introducing an infection into the kidney or by a nephrostomy wound plus an infection, even though the renal wound heals and the infection later clears. Cases in which the kidney is already damaged by obstruction ideally speaking, should have surgical correction without drainage and the resulting temporary infection or a cortical injury by a nephrostomy. Such surgery demands careful and painstaking technique. Few authors indeed there are who advise the primary closure of a pelvic incision without drainage of the urinary tract. The risk of a bad result looms large to the uninitiated but the purpose demands exacting surgery which we must promote if we are to progress in renal surgery. Hypothetically the idea is sound and should be recommended and executed more often because we see patients who come without infection who are operated upon and are left with an infection which is never controlled.

JOHN A. LORR, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES TENDONS ETC

De Leo, F. A Contribution to the Pathogenesis of Volkmann's Ischemic Paralysis (Contributo alla patogenesi della malattia di Volkmann) *Chir org movim* 1946 30 90.

The author shows a series of microscopic sections of tissue specimens taken from muscles afflicted with Volkmann's ischemic paralysis. He shows the various grades of muscular changes from mild hyperplasia of the connective tissue, through the stages of collagenous infiltration about the muscle fibers to complete replacement of the muscular elements by fibrous tissues to a condition which he calls *cirrhosis muscularis*.

After a review of the literature and on the basis of his personal experiences, the author states that it is his opinion that the etiology of Volkmann's ischemic paralysis is pressure produced by hemorrhage and edema in the cubital area of the arm which becomes encased by the deep fascia of the arm until there is a definite ischemia of the nerves in the elbow region usually involving both the median and radial nerves.

For this reason the author believes that the only treatment for Volkmann's ischemic paralysis is a long sitting of the deep fascia of the arm with exposure of both the median and radial nerve roots in the cubital area. He believes that by this method only can the numerous trophic changes which occur in the hand be avoided and also only by this means can the marked destruction of the muscle tissue be prevented. He goes into considerable detail as to why he believes that the prime etiology is not, in itself due to vascular impairment but to direct pressure on the nerves with resulting trophic changes.

CARLO SCUDERI M D

Cahuzac, M., and Jung, F.: Contusion of the Humeral Artery; Spasm of the Vessels; Volkmann's Syndrome (Contusion de l'artère humérale. Spasme vasculaire. Syndrome de Volkmann) *Rev orthop* Par 1946 39 241

A child of 10 years fell on her wrist while playing and fractured her right elbow. This was on September 4. There was great pain at the site of fracture and the arm was cold and dead below it.

The roentgen examination showed a supracondylar fracture of the elbow and physical examination revealed all the typical nervous and vascular complications. Because of repeated fainting spells operation was delayed until the next day.

An incision over the internal bicipital groove showed that the humeral artery and the median nerve were contused. When the artery was freed the circulation appeared to be restored to normal and the fracture was reduced. Recovery seemed to be pro-

ceeding normally until September 17 when the child complained of intense pain in the forearm and coldness and pallor of the hand. As a stellate ganglion injection could not be made on account of the child's intense fear a peribulbar injection of novocain was given above the cast. On October 6 the cast was removed. On December 4 the hand was cold and violet colored and on slight extension of the wrist, the fingers contracted spasmodically in a typical Volkmann's contracture. Active movements were very limited.

Therefore 3 months after operation for a supracondylar fracture with contusion of the humeral artery and median nerve there was a typical Volkmann's syndrome due to vessel spasm. Ten peri-bulbar infiltrations of novocain were given and the child gradually recovered.

This case shows all the typical results of arterial spasm and it also shows the efficacy of operations on the sympathetic nervous system in Volkmann's contracture. This syndrome begins slowly and surgery of the sympathetic nerves may cure or improve the condition for a long time after the accident. In this case the authors believe that the early operation with release of the constriction of the artery prevented the development of a much more serious picture. Probably a sympathectomy at the time of the initial operation would have prevented any contracture.

AUDREY G MORGAN M D

Morandi, G.: The Indications and Results of Surgical Reconstruction of the Thumb (Indicazioni e risultati della ricostruzione chirurgica del pollice) *Chir org movim* 1946 30 41

The author reports on 17 cases which came under his observation at the Putti amputation center at Bologna. Two cases involved the upper extremity after the thumb had been lost and 15 involved both upper extremities.

The operative procedure which he recommends is the surgical removal of the second and third metacarpal bones which leaves a sufficient amount of skin for the closure of the cleft resulting from prolongation of the depth of the web between the first and second metacarpals. In addition it gives a space that is sufficient for the production of grasping power; this power is limited if the second and third metacarpals are not removed.

There are 25 illustrations in this article showing the 'before and after findings in a number of cases.

There is no question that with the removal of the second and third metacarpals the hand is smaller but there is definitely a thumb that can be brought over to grasp something against the remaining fourth and fifth metacarpal bones.

In all 17 cases a very satisfactory result was obtained. The author stresses the point that this pro-

cedure is much less formidable and the period of disability of the patient is far shorter than in any other form of thumb reconstruction that has been recommended in the past, such as the transplantation of tibial grafts covered by skin or transplantation of the toes into the stump of the thumb.

CARLO SCUDERI, M.D.

Cabrea, G : Spondylolisthesis (Spondylolysis) *Clin. org. mens.* 1946 30 57.

The author gives a very fine résumé of the historical background of spondylolisthesis. He presents 10 cases of his own.

The author gives a very excellent review of the subject including a bibliography.

In concluding he states that spondylolisthesis should be treated by long immobilization in bed followed by local heat and massage and in some cases by the use of x rays. The patient is then permitted to be up and about, always wearing a plaster jacket that is light and very form fitting. Under this regimen the majority of the patients are relieved of pain in the area of the spondylolisthesis. Although the author discusses the different forms of spinal fusion in detail, he does not suggest it as treatment and in none of his cases was any spinal fusion performed.

CARLO SCUDERI, M.D.

Martin, P : Pyogenic Osteomyelitis of the Spine. *Brit. M. J.* 1946 688.

Pyogenic osteomyelitis of the spine is approximately three times more common in males than in females, and usually the age of onset is in the third decade; that is, after the vertebrae are fully formed thus differentiating it from osteomyelitis occurring in the long bones. There is no true epiphyseal growth in the vertebral bodies such as one finds in the long bones. This may account in part for the occurrence of the condition in the third decade or later.

These cases are often so acute and fulminating, and toxemia is so intense that an antemortem diagnosis is not made. The author believes that in many cases the condition labeled tuberculous of the spine, which responds so well to early firm bony fusion is in reality a pyogenic osteomyelitis.

The lumbar region is most frequently involved and the bodies of the vertebrae are generally affected. This is usually a metastatic phenomenon the primary focus being recognizable in about one-half of the cases as a topical infection such as a boil, whitlow, tooth infection, septic wound or another focus of osteomyelitis. The causative organism if it can be obtained directly or by blood culture or from the primary focus is a *Staphylococcus aureus* less commonly a *Staphylococcus albus* or rarely a streptococcus.

The treatment for pyogenic osteomyelitis is immobilization of the spine preferably in a plaster bed until the disease process has subsided and bony fusion is complete. Penicillin is advocated both locally and systemically. If abscesses form, evacua-

tion is recommended. A fusion operation is thought to be unnecessary.

A series of 4 cases is reported.

C. FRED GONZALEZ, M.D.

Deitama, F : Localization of Paget's Disease in a Single Vertebra (La localizzazione vertebrale isolata nel morbo di Paget) *Clin. org. mens.* 1946 30 33.

Several diseases have been named for Sir James Paget, a distinguished English physician and student of surgical pathology. In this article the author discusses Paget's osteitis deformans. He collected 110 cases from the Rizzoli Institute, the Orthopedic Clinic of the University of Bologna. Twenty of these cases are described and illustrated with roentgenograms. In 10 of these cases the lesion was localized in a single vertebra while in the remaining 10 several vertebrae or other parts of the skeleton were involved.

The disease is probably of endocrine and sympathetic origin, although the chief factor is not known. Clinically there is loss of teeth, deafness, difficult nasal respiration, change in the form and size of the skull and bones of the limbs, rheumatoid pain, and a condition of asthenia. Differential diagnosis is impossible, however, without an accurate knowledge of the roentgen picture of the affected bones. In the case of disease of the vertebrae the affected vertebra shows a dense structure like that of marble (osteolytic type) or large trabeculae arranged irregularly and more transparent than normal (osteoporotic type) because they are made up of osteoid tissue. The vertebra is often enlarged and flattened out between the two adjoining ones. Sometimes the two forms are combined. In advanced stages of the disease the hypertrophy of bone is often extreme.

ARNOLD G. MORAN, M.D.

Dundon, C. G., Williams, H. A. and Lippitt, T. C : Eosinophilic Granuloma of Bone. *Radiology* 1946 47 433.

The authors analyze the literature on 48 cases of eosinophilic granuloma of bone and add 5 cases of their own.

The condition occurs more frequently in males, in the ratio of 5 to 1. The age of the patients ranges from 6 months to 58 years. Thirty-four of the patients were under 30 years and 10 were under 10 years. Nearly all of the bones proximal to the wrists and ankles were involved. Thirty-six patients had single lesions and in 36 per cent of these the skull was involved and in 16.6 per cent the ribs and femurs. Most patients had from mild to severe pain, swelling of the soft tissues, and tenderness to pressure. A few patients had mild systemic reactions, fever, anorexia, lassitude and weight loss.

Laboratory examinations showed essentially normal conditions except for slight leucocytosis and occasional eosinophilia of from 4 to 31 per cent. Roentgenographic examinations showed round, oval, or irregular areas of decreased density usually from

Fig. 1 (Delitala and Pals) Diagrammatic operative procedure for reduction and arthrodesis.

The operative approach which is recommended by the authors is a lateral incision extending from the crest of the ilium down along the line of cleavage between the tensor fascia femoris muscle and the gluteus medius muscle along the anterior aspect of the shaft of the femur for a distance of about 4 inches. Then by subperiosteal dissection the gluteus medius, minimus and maximus, are retracted posteriorly and the tensor fascia femoris is retracted anteriorly. The capsule is then exposed and cut by a T incision with the base along the intertrochanteric line. This permits a good exposure of the head and neck. The iliopsoas muscle is then cut at its attachment to the lesser trochanter. The cartilage from the head is removed and the acetabulum is drilled out so that all cartilage has been removed and the fresh bone of the head and acetabulum are brought in contact. Then by use of a motor saw the greater trochanter and a portion of the upper part of the shaft of the femur are cut and the Hibbs procedure is used for performing the arthrodesis of the hip by inserting the reversed end of the greater trochanter femoral shaft portion of bone into just above the superior lip of the acetabulum. The patient is then immobilized in a hip spica until such time as the x rays show a solid bony union of the arthrodesis.

The author states that it is imperative that the Iliopsoas tendon be severed from the lesser trochanter otherwise it is most difficult to obtain a sufficient looseness of the hip articulation to produce a satisfactory reduction and replacement of the head in the acetabulum with sufficient abduction to maintain a good position of the arthrodesis of the hip. The authors also state that because of the fact that there is an actual lengthening of the leg from its previous position, it is necessary to keep the knee flexed at least to an angle of from 45 to 50 degrees at the time that the cast is applied so as not to produce vascular and nervous changes in the extremity. The knee is extended at the end of 2 months when the cast is changed and then another cast is applied which is maintained for a period of 3 to 5 months thereafter

until such time as x ray evidence of a solid bony union occurs.

The authors are reporting on their experience with 10 operative cases. The patients ranged from 14 to 30 years of age. One case was followed up for a period of 20 years.

CARLO SCUDERI, M.D.

Pals, C.: Secondary Osteosynthesis in Operative Elongation of the Femur (Osteosintesi secondaria nell'allungamento operativo del femore) *Chir. org. movim.* 1946 30 159

The author describes an improved method of lengthening the femur. After a certain period of traction an oblique osteotomy is performed and a stainless steel wire is run through the apposed surfaces of the fragments. A plaster cast is then applied. This method has proved very satisfactory in his hands. The danger of infection is no greater than in any operative procedure and the occurrence of infection is a reflection on the surgeon's skill and care rather than on the method.

Illustrations showing the exact technique of applying the wire and roentgenograms of the cases operated on, showing the exact degree of lengthening obtained, are given in the original article. As compared with Pott's method the necessary period of immobilization is reduced by half—from 6 months to 3.

Giuntini L.: Surgical Mobilization of Rigid Joints with Interposition of Absorbable Membranes (La mobilizzazione chirurgica delle rigidità articolari con interposizione di membrane assorbibili) *Chir. org. movim.* 1946 30 216

Various living tissues, including muscle, aponeurosis, fat and tendons have been used in joint surgery to prevent recurrent ankylosis. The author has been experimenting with the use of gelatin for such interpositions. He has used it in experiments on rabbits and describes 2 clinical cases in which it was used one involving the elbow joint and the other the ankle. His work is illustrated.

1 to 4 cm. in diameter. The lesions produced expansion of the bone in 5 cases and perforation of the cortex in at least 5 cases. Periostitis was present in 14 cases, and 3 lesions had sclerotic margins.

At operation the early lesions contain soft, friable yellowish brown and red material. Microscopically, the characteristic cell is a large mononuclear cell with granular cytoplasm. There are a variety of other cells, including large numbers of eosinophils. Treatment by surgical excision, curettage or irradiation has given good results. No death has been attributed to the disease. VERNON C. TURNER, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Renon, C. and Calvez, L. Screwing the Ruptured Tendon of the Long Portion of the Brachial Biceps into the Diaphysis of the Humerus (*Le suture diaphysaire dans les ruptures de la longue portion du biceps brachial*). *Rev. chir. Par.* 946, 3 253.

Rupture of the tendon of the long head of the biceps may result from violence or it may occur in longstanding arthritis of the shoulder without any unusual effort. The authors describe a case in a man of 42 years who on lifting a sack weighing 75 kgm. felt intense pain and a tearing sensation in the left arm. Examination revealed rupture of this tendon.

The authors recommend screwing the end of the ruptured tendon into the humerus in the bicipital groove at the level of the muscle insertion to accomplish fixation of the fleshy body of the muscle in the normal position. The thing to be avoided is too low fixation of the ruptured tendon. It is simple and easy. The review of a case operated on in this way 18 years ago shows that there is no injury to the bone from the screw. A Lambotte screw 3 cm. long is passed through the tendon; needless to say the tendon must be sufficiently solid and intact so that the screw can be passed through it without tearing. An opening for the screw is made in the humerus with a perforator and the screw fixed in it. The arm is then kept in plaster for 3 weeks with the elbow at a right angle.

Blondin and Roy have recently recommended suture of the ruptured tendon to the anterior branch of the V-shaped insertion of the deltoid tendon. The authors do not advocate the complete replacement of this method by that of screwing. Both have their indications. AUDREY G. MORGAN, M.D.

Gherlinzoni, G. (Surgery of Spastic Deformity of the Wrist and Hand (Contributo alla chirurgia delle deformità spastiche del polso e della mano). *Chir. org. mod. 946* 3 176.

The results of surgery in spastic deformity of the wrist and hand have been so poor that many surgeons have given up all attempts at surgical management of this condition. Statistics from the Orthopedic Hospital in Los Angeles show that among 1000 cases

of spastic deformity in childhood, 542 operations were performed—only 65 of these were on the upper limb, 21 on the wrist and 10 on the hand.

The author discusses 25 cases operated on at the Rizzoli Institute, the Orthopedic clinic of the University of Bologna, for spastic deformity of the wrist and hand resulting from the tetraplegic form of Little's disease and infantile cerebral hemiplegia. Some of these cases were caused by spasm of the muscles of the forearm and others by spasm of the muscles of the hand itself. The degree of flexion of the wrist varied from a very slight one to one so extreme that the palm of the hand rested against the forearm. The operations performed in these cases were plastic elongation of the flexors of the wrist, arthrodesis of the wrist, capsuloplasty of the radiocarpal joint with tendon fixation of the radial extensors and tendon transplantation at the wrist.

The latter operation was performed in 15 cases. In the great majority of the cases the tendons transplanted were two—those of the palmaris longus and of the anterior cubital muscles, the former being fixed to the extensor pollicis longus, the radialis, or the extensor communis, and the latter chiefly to the extensors ulnaris or radialis of the wrist. Cases are illustrated, showing just what tendon transplantations were made and the results of the operations.

Tendon transplantation is the preferred operation in these cases. The esthetic results were good in all, the deformity being permanently corrected. In 8 of the cases a certain degree of function was restored. Complete restoration of active motility is not to be expected.

Cases for operation must be carefully selected. Those in which brain function is too much affected or in which choreoathetoid manifestations or deformities of the bones and joints are present must be excluded. AUDREY G. MORGAN, M.D.

Delitala, F., and Pais, C.: The Reduction and Arthrodesis of Old Unilateral Congenital Dislocations of the Hip (La riduzione-artoidei delle lussazioni congenite inveterate unilaterali dell'anca). *Chir. org. mod. 946* 3.

The authors definitely believe that old congenital dislocations of the hip which are unilateral in type should be fused once they begin to give manifestations of progressive pain, deformity, and poor walking habits. No other method do they think, gives as gratifying a result and as great a possibility of success as arthrodesis. The freedom from pain, the stability of the hip and the better walking habits of individuals with old dislocations of the hip certainly more than compensate for the loss of motion in this one articulation.

The authors believe that an arthrodesis is far preferable to the old Lorenz bifurcation operation or subtrochanteric osteotomies which are performed by some men. In a few selected cases they believe that the shelf operation is of value—when there is a fairly good acetabulum and not much evidence of subluxation or osteoarthritic changes associated with pain.

Murray G. End Results of Bone Grafting for Nonunion of the Carpal Navicular. *J Bone Surg* 1946, 28 749

The author presents the results in 100 cases in which bone grafts were used for nonunion and fractures of the carpal navicular bone. Excellent results with good function of the wrist were obtained in the majority of the cases.

The author suggests that certain principles must be followed to obtain the best results. The bone graft must be large and well placed so that both fractured fragments are well approximated. The drill hole must be made so that the surrounding articulations are not involved. The fractured fragments must be impacted and the graft so placed that it holds the fractured fragments in good apposition. The splint must include the wrist and all metacarpals, and the proximal phalanges so that the normal movements are completely prevented for a minimum of 10 weeks. Immobilization must be continued until there is x-ray evidence of union of the graft to both fragments. The bone grafts in this series were usually taken from the tibia.

A table is included showing the data on 100 cases of bone grafting for nonunion of the carpal navicular bone. There were 4 cases of nonunion after bone grafting.

The contraindications to bone grafting for nonunion of the navicular are (1) recent fractures and (2) arthritis in the wrist. Considerable bone grafting of the navicular does not lessen the tendency toward arthritis in the wrist.

The functional end results in these cases were excellent.

RICHARD J. BENNETT JR., M.D.

Larot, J.: Pathological Luxations of the Hip Following Osteoarthritis in Infants (Luxations pathologiques de la hanche consécutives à l'ostéoartrite du nourisson). *Rev orthop* Par 1946 33 213.

The hip is the joint most frequently involved in osteoarthritis in infants. The disease is generally seen in the first few days or the first few months of life. The author's 14 patients were seen later for the sequelae of the osteoarthritis, that is, dislocation of the joint surfaces. The 14 cases are described and illustrated with roentgenograms.

Operation was performed in all cases as nonoperative reduction is practically impossible in these cases. The causative organism of the osteoarthritis is generally the streptococcus, although some cases have been known to be caused by the staphylococcus aureus. The beginning localization of the disease is in the bone on the metaphyseal side of the joint cartilage.

Ombredanne and Longuet say that there is luxation in almost all cases, but among the author's 14 cases there were only 2 of luxation and 12 of subluxation. The capsule is generally preserved which is important in reconstruction of the joint. The acetabulum is preserved and lined with cartilage and frequently contains membranous adhesions. The

head and a considerable part of the neck are destroyed.

The author's aim is to restore the reconstructed neck to the acetabulum and provide for its fixation at that point. The steps of the operation are illustrated. A transtrochanteric incision is made and the capsule is incised circularly near the base of the neck. When the joint is opened the adhesions are removed from the acetabulum. The difficult part is the preparation of the upper end of the femur. The chondrophytes which adhere to the stump of the neck are removed and the obliquity of the neck is restored by an incision like that of Whitman's operation. White wax is used for hemostasis of the bleeding surfaces. The segment of the neck is introduced into the acetabulum in marked abduction. The operation is terminated by careful fixation of the capsule to the base of the neck. The joint is kept in position for about 6 weeks with a plaster cast.

A secondary osteotomy of the neck is performed after about 3 months in cases of subluxation and after from 4 to 6 months in those of complete luxation. In the first case the osteotomy was performed at the time of the first operation but the neck was absorbed therefore it is performed secondarily now. In some cases the limb had a marked tendency to assume a position of flexion-adduction. In such cases the patient should wear a leather apparatus to keep the hip in good position for about a year. The operation should be performed at an early age about 3 years.

ALEXANDER G. MORGAN, M.D.

Turner C. G.: Stable Osteosynthesis. Personal Experience with Kuentzsch's Method (La osteosíntesis estable. Experiencia personal con el método de Kuentzsch). *Rev españ cir* 1946 3 93.

Kuentzsch introduced the so-called nailing of bone marrow which employs a steel nail containing 8 per cent of nickel and 18 per cent of chrome. Such a nail does not undergo any changes in the body and is resistant to corrosion. Unlike the nails made of other kinds of steel such a nail does not produce an electrolytic reaction. The transverse section of the nail is V shaped. Either straight or curved nails may be used according to the location of the fracture. The function of osteoblasts is not altered by the presence of the nail. Vitallium may also be suitable for such purposes although it is not as resistant as steel. On the other hand, tantalum, because of its physical properties cannot be used for bone marrow nailing. Plastic substances, which are derivatives of acrylic resins, are not sufficiently resistant and durable.

A straight nail is applicable when the transverse diameter of the medullary cavity is uniform in the entire bone. This is the case in the diaphysis of the femur. On the other hand the humerus has the conical shape of the medullary cavity with the narrow side pointing upward; therefore, a nail introduced in the region of the fossa of the olecranon can immobilize sufficiently only a fracture of the lower third of the humerus. In the lower portion of the tibia an hour

As gelatin is closely related physicochemically to synovial fluid and as it is easy to prepare and apply it would seem to be the best physiological agent for this purpose. The clinical cases in which the author used it presented absolute rigidity of the involved joint from an old fracture or another injury. The gelatin, which is an organic extract of bone and cartilage, is dissolved in 40 parts of water and boiled for from 45 to 60 minutes until the solvent is completely dissolved. It is then spread on sterile dishes to form a thin layer and after cooling and condensation this thin layer of gelatin is spread over the bleeding joint surface which has been produced by operation. The gelatin prevents the formation of connective tissue which would reproduce rigidity and the joint remains mobile.

In the author's cases this mobility has persisted for from 4 to 5 months after operation but it will require more time to tell whether the mobility will remain permanent. If it does, this method of interposition should prove useful in other operations, such as operative elongation of the femur and osteotomy of the neck of the femur for coxa vara or valga, in which it is necessary for the two bone fragments to move on each other. The author knows of no other substance so well adapted to prevent too early fusion as gelatin. AUGUST G. MORRIS, M.D.

FRACTURES AND DISLOCATIONS

Patrick, J.: A Study of Supination and Pronation, with Especial Reference to the Treatment of Forearm Fractures. *J Bone Surg* 94b, 35 737

This study is based on 6,000 fractures of the forearm treated during the past 12 years. There are also included nontraumatic cases with limitation of rotation due to other causes. 1,245 cases presenting more than slight limitation of rotation were particularly investigated. Normally the range of rotation seems to decrease with age, there being a wide variation in the normal range of supination and pronation. Pronation shows the greater individual variation and in normal adults may be as little as 30 degrees. Supination is rarely less than 70 degrees. The interosseous border of the ulna can be regarded as corresponding to the line of the axis of rotation of the radius.

Six hundred and thirty-seven forearm fractures excluding those with imperfect reduction or malalignment were studied for the average combined limitation of supination and pronation for fractures of the radius and ulna, respectively at the different levels, with the exception of some fractures of the head of the radius. Fractures above the level of the interosseous membrane do not cause limitation of rotation after union has occurred. This is true also of fractures of the radial styloid. Cases of Colles fracture show limitation of rotation.

This problem was investigated by taking arthrograms of the joint space between the head of the ulna and the fibrocartilage. In the fractures with limitation of rotation some degree of obliteration of this joint space could be demonstrated. Measurements

showed that limitation of supination was usually twice as great as limitation of pronation. This degree of limitation is quite unpredictable. There appears to be no relation between the degree of the original displacement and the extent of loss of rotation. Nor does perfect reduction necessarily insure a full return of rotation. Most fractures of the head of the radius produce no limitation of rotation. Even careful excision of the head of the radius gives very few degrees of limitation of rotation.

In fractures of the radius and ulna at the level of attachment of the interosseous membrane there will be some loss of pronation. The restriction of rotation in isolated ulnar fractures is rarely permanent. Callus or fibrous tissue extending into the interosseous membrane from the radius cannot affect the range of rotation of the radius. It was found that the attachments of the articulating discs were torn and caused the disability. Isolated fractures of the shaft of the radius with displacement demand careful treatment. In fractures of the shafts of the radius and ulna above the level of the interosseous membrane there was no loss of supination or pronation after the fractures had united. During the past 5 years 33 cases of fracture of the head of the radius have been treated by excision with the result that there has been an almost complete return of rotation. Open operation of fracture of the ulna may result in an increase in callus and fibrous tissue around the fracture and, unless absolutely necessary, operation should be avoided. The author incorporates a callos bandage in the last layer of plaster just below the elbow joint and suspension is carried out from this level. With this method, there have been no cases of angulation occurring under plaster.

In cases in which cross union in the lower one-half of the forearm between the radius and ulna have occurred, the treatment consists in excision of 1 inch of the ulna at the site of fracture as well as of the mass of callus between the bones. A full range of supination and pronation is obtained. When cross union has occurred in the middle third of the forearm, treatment is difficult. Here it is necessary to excise 1½ inches of the ulna with callus. After 3 months, a whole thickness fibular graft may be inserted across the gap. When severe permanent limitation of rotation develops after Colles fracture, excision of the head and neck of the ulna is suggested as a reliable way to recover full rotation. Twenty of 24 patients undergoing such operations were finally discharged without any complaint of disability. Volkman's contracture can be improved by physical therapy.

When there is loss of rotation in paralytic and spastic states, a curvature of the shaft of the ulna may develop. Considerable improvement in the range of rotation can be obtained by performing an osteotomy on the upper third of the ulna and realigning the shaft so that the interosseous border conforms to the axis of rotation of the radius. This is best accomplished by forcing the forearm into full supination or pronation after osteotomy and fixing it in plaster. RICHARD J. BENNETT, JR., M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Stowers, J. M. and Grossman M. E.: Thrombosis of the Inferior Vena Cava. *Lancet* Lond. 1946 2 868.

The principle of proximal ligation in the treatment of venous thrombosis whether it be for a spreading thrombophlebitis or a silent phlebothrombosis of the lower limbs is currently gaining favor. Appropriate ligation of the inferior vena cava for venous thrombosis of the pelvic veins has been recommended by DeBakey and others as a lifesaving procedure in some cases. It combats the chance of pulmonary embolism or possibly the sudden extension of the thrombus to occlude both renal veins.

Formerly thrombosis of the inferior vena cava was regarded usually as an incidental happening difficult to diagnose and in any case, of little more than academic interest. The authors believe however that thrombosis of the inferior vena cava may be more common than is realized and that great practical surgical importance may now rest upon a reliable method of diagnosis.

The authors describe in detail a technique of phlebography in which a radio-opaque substance diodone is injected into one of the tributaries of the sphenous vein near its junction with the femoral vein and roentgenograms are taken during and immediately after the injection. Sensitivity to diodone is carefully determined by either the intradermal method or the ocular method. As a final safeguard, 2 c.c. of diodone are injected intravenously and the patient is observed for untoward reactions.

A neat maneuver, used by the authors to enhance the radio-opacity of the phlebograms is the employment of a blood pressure cuff below the site of injection thereby decreasing the dilution of diodone with venous blood from the limb. About 20 c.c. of 70 per cent diodone is injected through an 18 gauge needle in about 20 seconds. Films are taken at 5, 15, 25 and 35 second intervals after initiating the injection.

Two case records are reported in which diodone successfully demonstrated the occlusion of the inferior vena cava. The question of the practical importance and technical performance of this method in the presence of a thrombosis of the inferior vena cava, when it occurs in association with iliac and femoral thrombosis was not discussed.

EDWARD F. LEWISON M.D.

Elkin, D. C.: Exposure of Blood Vessels. *J. Am. Coll. Surg.* 1946 133 431.

The author is desirous of emphasizing the importance of knowing the anatomical relationships of vascular trunks in order to perform operative procedures on the blood vessels intelligently and safely. Adequate exposure is essential but the placing of

Fig. 1 (D. C. Elkin) Subperiosteal resection of the clavicle for exposure of vessels at the base of the neck.

Fig. 2. Exposure of the vessels at the base of the neck. The medial half of the clavicle has been removed. Medial retraction of the carotid sheath exposes the vertebral and thyrocervical vessels at their origin. Further exposure is obtained by dividing the scalenus anterior muscle (after Henry).

the skin incision must conform to recognized surgical principles.

The methods of exposure of most of the major vascular trunks are described with subperiosteal resection of a clavicular segment and of the fibular head to expose the vessels at the base of the neck and the proximal portions of the tibial and peroneal vessels respectively. It is neither necessary nor advisable to replace these resected segments. The most difficult exposure described is that of the vertebral vessels because of the deep position in which they lie in the neck and because of the vital nature of the surrounding structures. The approach to the vessels lying within the thoracic cage is difficult because of the

glass constriction of the medullary cavity is usually found and this narrow space interferes with the introduction of the nail.

The V-shaped nail causes only a minimal irritation of the medulla. Usually eosinophilia, more pronounced in children than in adults, follows the introduction of the nail. The sedimentation rate is usually accelerated but no effect on the amount of hemoglobin or on the number, size, or shape of red or white blood corpuscles could be observed. Eosinophilia is attributable to the irritation of the red bone marrow of the epiphysis in the vicinity of the nail.

There is no unanimity of opinion as to whether the nail favors or inhibits regeneration of bone.

The introduction of the nail is not difficult for an experienced bone surgeon. A strict observance of technical rules laid down by Kneutcher is essential.

The author has never observed fat embolism which was attributable to the introduction of the nail into the bone marrow. Infection of the fracture is possible if strict asepsis is not observed. As a rule such infections are mild because the area is immobilized; the medulla possesses a strong bactericidal action, normal nutritional and circulatory conditions of the involved region are maintained and the metal apparently inhibits the progress of infection. Lane's technique is advisable and a local application of sulfathiazole is recommended by the author. Frequently a transient

stiffness of the articulation distal to the fracture is observed. Such stiffness as a rule disappears spontaneously within a few weeks. The stiffness may be accompanied by edema and may be interpreted as a reflex sympathetic dystrophy.

The indications for the introduction of the nail are as follows: (1) fractures in patients whose age or general condition make prolonged immobilization undesirable; (2) spontaneous fractures caused by nonmalignant processes; (3) transverse fractures of the diaphysis which frequently show a tendency to lateral displacement; (4) fractures which can be easily reduced but are difficult to maintain in good apposition; (5) fractures of a diaphysis with an annular fragment; (6) fracture dislocations of the neck of the humerus; (7) pseudarthrosis, fractures with delayed consolidation, and osteotomies; and (8) compound fractures of recent origin.

As to the use of the nail in spontaneous fractures caused by malignant tumors, there is a potential danger of propagation of the tumor due to pressure exerted by the nail on tumor cells.

The nailing favors excellent results in transverse fractures of the middle third of the femur.

The method is contraindicated in infected fractures and those of infancy and adolescence because of the danger of impairment of the functions of the bonyopoeitic system.

overlying structures and the difficulty is enormously increased in the presence of an aneurysm or arteriovenous fistula because of the danger of hemorrhage. The adequate exposure necessary here is gained only by resection of portions of the first and second ribs and of a segment of the sternum in addition to removal of part of the clavicle.

The methods of exposure of the larger vessels in the extremities are also described.

EDWARD H. CAMP, M.D.

Gordon, L. Z., and Thurber, D. C.: Temporal Arteritis: Report of a Case and a Comparison with Respect to Periarthritis Nodosa. *Arch. Path. & Clin.* 1945, 4, 4.

First described in 1932, temporal arteritis has been reported occasionally in the literature as a definite clinical and pathologic entity. A great diversity of symptoms has been described with this condition including fever, anorexia, malaise, anemia, weight loss, and pain along areas of the temporal arteries and over the scalp, and it has generally been found that the condition is associated with widespread involvement of the arterial tree, the aorta, and the carotid, subclavian, cerebral, and iliac, as well as temporal arteries.

A case of temporal arteritis is described and a pathologic comparison is made between this condition and periarthritis nodosa. The case was that of a 65-year-old white laborer whose chief complaint was severe headache and pain over both temporal regions.

He further stated that he had had severe pain in his thighs 3 months previously. Thickened, tender, and pulsating temporal vessels were seen. Other findings were negative except for thickened radial and pedal arteries. Temporal pain subsided abruptly on the second hospital day; the constitutional symptoms cleared, and 8 months later when the patient was seen he was asymptomatic. A biopsy of the temporal arteries on the fourth hospital day revealed that the walls were thickened and infiltrated with lymphoid cells; the internal elastic membrane was reduplicated, pigmented, and destroyed in places, and the media was edematous and infiltrated with lymphocytes and plasma cells with occasional small areas of necrosis. The specimen had the appearance of a granulomatous lesion. It was concluded that the patient had suffered from a generalized arteritis, with progressive involvement of different arteries.

The authors concluded from a review of the literature and their own findings that every histologic picture described in temporal arteritis so far can be found in periarthritis nodosa. It is impossible to differentiate the two conditions on the basis of cellular responses; both conditions go through destructive and reparative phases which are similar. The statement that there is specifically an axial spread in temporal arteritis and a local lesion in periarthritis nodosa has been controverted in many instances.

The differences between temporal arteritis and periarthritis nodosa are as follows: (1) periarthritis nodosa involves the visceral and only less commonly

a few of the medium sized and smaller peripheral arteries temporal arteritis has its predominant involvement in the aorta and in its larger branches (innominate carotid subclavian iliac as well as the temporal arteries) (2) temporal arteritis is observed twice as frequently in women as in men (3) temporal arteritis has never been reported in anyone under 55 years of age whereas periarteritis nodosa is most frequent in young adult males and (4) periarteritis nodosa is usually fatal whereas patients with temporal arteritis usually recover.

Periarteritis nodosa is called a misnomer by the authors, as occasionally the nodose character of the lesion is absent. Temporal arteritis is also incorrectly named as often the involvement is not limited to the temporal arteries and on occasion the temporal arteries may not be involved. It is suggested that periarteritis nodosa be called panarteritis predominately of the visceral arteries and that temporal arteritis be called panarteritis predominately of the aorta and its peripheral branches.

PHILIP B. CHASE, M.D.

BLOOD TRANSFUSION

Leffebvre F. Transfusion and Autotransfusion of Oxygenated Blood in the Treatment of Asphyxia, Electrocution Drowning and Carbon Monoxide Poisoning. (La transfusion et l'autotransfusion oxygénée dans le traitement des asphyxies, électrocutions, noyades et intoxications par l'oxyde de carbone) *Presse méd.* 1946 54 833

In cases of asphyxia artificial respiration often fails for two reasons:

1. In many cases, especially in drowning the lower portion of the respiratory tract is obstructed because of the aspiration of water or other substances and the walls of the alveoli are adherent to each other like two sheets of wet blotting paper; this prevents the oxygen from passing into the lung capillaries.

2. Even if the lower respiratory tract is free and oxygenation of the pulmonary blood by artificial respiration is possible this blood does not circulate in the systemic circulation when the heart has stopped beating as in electrocution or reflex collapse.

In these conditions it appears more rational to inject oxygenated blood directly into the heart, rather than to try artificial respiration. The author experimented on cats which were kept under water

for different periods up to 30 minutes. Then the thorax was opened for observation of the heart and a few cubic centimeters of oxygenated blood were injected intracardially. In all of the cases the heart started contracting again the cyanotic color of the muscle changed to bright red and systemic circulation could be observed. After the oxygen had been exhausted, the contractions stopped. This experiment can be repeated any number of times in the same individual.

On the basis of these experiences the author developed the following routine for the purpose of resuscitation.

Oxygenated blood is injected intracardially. One minute later, the cardiac muscle is stimulated electrically. This proceeding is repeated in the same order until contractions of the heart set in. After the beginning of heart pulsation, the injection of oxygenated blood is continued by the intravenous way. The blood is supplied either by heterotransfusion or autotransfusion. The latter method is preferable, except for cases of severe hemorrhage as the amount of available blood is not limited. The blood is drawn from the femoral vein and passed through the oxygenating apparatus before being reinjected either in the heart muscle or in the vein. The author considers this as the method of choice in all cases in which the cardiac muscle is in a condition of asphyxia without lesion of an organ (electrocution syncope during anesthesia).

The treatment of carbon monoxide poisoning by autotransfusion presents a special problem. Since the affinity of carbon monoxide to hemoglobin is 210 times greater than that of oxygen blood which had been exposed to carbon monoxide cannot be oxygenated in the usual oxygenation apparatus. To substitute the oxygen for the carbon dioxide, oxygen has to be brought in contact with the blood under high pressure. The development of this method is still in the experimental stage and has not been applied to clinical cases.

Altogether it seems that the work of the author has not gone beyond the stage of animal experiments since he does not mention any experiences with cases of asphyxia in man. He reports however that Vladimir Negovsky in Russia has developed a similar method which was applied successfully to wounded soldiers. Of 51 patients who were considered lost 12 were resuscitated by autotransfusion of oxygenated blood.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Baronofsky I. D., Treloar A. E. and Wanger
ateen O. H.: Blood Loss in Operations: A Sta-
tistical Comparison of Losses as Determined
by the Gravimetric and Colorimetric Methods.
Surgery 1946, 20, 76

Earlier methods for the determination of blood loss in operations involved colorimetric estimations by the acid hematin method of blood washings from sponges, linens, and instruments. The latter test could be done only after the completion of the operation. Further, there was no direct correlation between the amount of blood lost and changes in hematocrit, hemoglobin and plasma protein concentration.

In the present investigation the blood loss from various operations was determined by the gravimetric method by means of a small weighing scale used directly in the operating room. Only dry sponges were used. The average weight of a 4 by 8 centimeter Curity ray sponge was 6 grams and that of the laparotomy ring sponge, 23 grams.

The results from the gravimetric method were compared with those obtained by the colorimetric method. The average blood loss during appendectomy was 25.8 c.c. during hernia, 82.0 c.c. during gall bladder operation, 179.4 c.c. subtotal gastrectomy, 456 to 500 c.c. thyroidectomy, 406 c.c., and pneumonectomy, 1,543 c.c. Comparison with the colorimetric method showed good agreement between the two tests.

BENJAMIN G. P. SHAPIROFF, M.D.

Abbott W. E.: Chemical Alterations Occurring in the Surgical Patient and Their Interpretations. *Surgery* 1946, 20, 770.

Methods for the correction of the chemical and physiologic disturbances in the sick and injured are not dependent on the accumulation of a large variety of laboratory data, but rather on the proper clinical interpretation of the metabolic disturbance. Although there are accurate chemical methods for the estimation of hemoglobin, cell volume, specific gravity of the blood and plasma, protein, etc., such values may become misleading especially when they are not paralleled by estimations of the circulating blood volume. It has been demonstrated that normal hematocrit values in males may vary between 41.8 and 52%. Blood studies often yield normal values in spite of obvious clinical states of malnutrition or dehydration.

In a study of 6 cases of gastric obstruction, hematocrit and plasma protein values were within normal limits but the plasma volume was subnormal and masked, by this dehydration, a reduced cell mass and a low total circulating protein. Postoperative edema, either the local or general type, is related to a variety of factors such as protein depletion, particularly of the albumin fraction, increased filtration pressure in

crossed capillary permeability, loss of tissue elasticity, kidney or endocrine dysfunction, lymphatic obstruction or postoperative salt intolerance. The administration of isotonic salt solution is often undesirable because a greater percentage of the ingested water is excreted, thus creating a hypertonic extracellular phase of salt which in turn causes the withdrawal of water from the cell. Such salt intolerance may result in death due to pulmonary or cerebral edema. The administration of half strength isotonic solution may produce a hypotonic extracellular phase with a shift of water to the intracellular deposits.

Normal plasma chloride or sodium concentrations may be obtained both in the state of dehydration and in overhydrated patients. Proof was presented that the degree of hydration or deficiencies of sodium chloride could not be determined from a plasma chloride estimation. Edema may appear in patient with a normal plasma protein concentration yet it may fail to appear in others with a low plasma protein concentration showing that water and salt consumption are equally important in the process of edema formation. In intestinal obstruction, dehydration and plasma volume reduction follows as a consequence of a reduced intake of fluid plus the loss of fluid by vomiting, distention, hemorrhage, transudation and infection. The prerenal azotemia or elevated urea nitrogen of intestinal obstruction is due to the lack of fluid necessary for the excretion of nitrogenous end products. In such cases, 4,000 to 5,000 c.c. of 10 per cent glucose in distilled water may be necessary to carry off the products of nitrogenous breakdown.

The author emphasizes that parenteral therapy should be dependent on the findings of a careful physical examination and the logical interpretation of a detailed history. In addition, blood chemistry as an accurate record of intake and output, plus the determination of the specific gravity, the chlorides, and the nitrogen in a 24 hour sample of urine, will serve to direct the kind and quantity of fluid the patient needs.

Dr. JAMES G. P. SHAPIROFF, M.D.

Gibson J. H. Jr. and Freeman L. W.: The Primary Closure of Decubitus Ulcers. *J Surg* 1946, 24, 48.

The surgical problem presented by a large decubitus ulcer is similar in many respects to a third degree burn with a full thickness skin loss. The end results of spontaneous healing and skin grafting are unsatisfactory because they do not provide full thickness skin and subcutaneous tissue over bony prominences.

A method of operative closure of decubitus ulcers described. It involves (1) complete excision of the ulcer, its margin and all pockets without contamination of the wound, (2) the formation of skin flaps in the immediate vicinity with curved borders and broad bases, (3) the rotation and advancement

of these flaps to cover the skin defect without ten-
sion and (4) the use of very fine cotton thread for
suture material.

Sixty-five ulcers were operated upon by this
method in 43 patients. Primary healing took place in
44, or 68 per cent, but the results could be regarded
as satisfactory in 59 or 90 per cent.

The author believes that complete excision and
immediate plastic closure is the best method of treat-
ing bedsores in young patients with paraplegia.

EMIL C. ROBINSON, M.D.

Fontaine, R., and Greiner-Oswald, A.: *Diagnosis of
Pulmonary Embolism, and Its Treatment Ex-
cept by the Method of Pulmonary Embolecto-
my (Identification et traitement des embolies pul-
monaires, l'embolectomie pulmonaire exceptée)* /
Chir. Par. 1946 62 249

Extensive animal experiments are described which
show that massive pulmonary embolism with ob-
struction of the trunk of the pulmonary artery as
described by classical writers really exists and that
it is found in approximately two-thirds of the cases
terminating in sudden death. However in about a
third of the cases with rapid death obliteration of the
circulation had not occurred in enough of the lung
surface to cause death in itself. The cause of death
in massive pulmonary embolism is not entirely me-
chanical death is partly due to reflexes originating
in the endothelium of the vessels and bringing about
vasoconstriction and dilatation of the right side of
the heart with stagnation of the blood in it.

The embolism may represent the whole of the
venous thrombus. Such thrombi are brought about
by slowing of the circulation, changes in the walls of
the veins, and changes in the blood. Surgery tends
to bring about such changes in the blood that it is
not astonishing that postoperative embolism occurs
but that it does not occur more frequently. Whether
or not a thrombus breaks off and forms an embolism
depends to a great degree on the rapidity of retrac-
tion of the clot; an excess of platelets favors retrac-
tion and therefore embolism. If the exact physico-
chemical changes in the blood could be determined
and prevented it would be possible to prevent embo-
lism entirely.

There are four typical forms of clinical picture in
acute embolism: the syncopeal form, the form accom-
panied by anguish, the form with cardiovascular col-
lapse and the form with respiratory asphyxia. Diag-
nosis is not too difficult in these classical forms but
there are atypical forms with hemiplegia or perito-
neal syndromes in which diagnosis is very difficult.
Most of the mistakes in diagnosis are made in these
forms.

As to treatment, the author does not discuss the
only really curative treatment: pulmonary embolec-
tomy as this is to be discussed by Redon in another
article. The prevention of venous thrombosis requires
careful and delicate handling in surgical operations.
Factors which tend to prevent venous stasis are early
exercise in bed, massage and elevation of the foot of

the bed. Early rising activates the circulation in the
lower limbs and in this way combats one of the fac-
tors of postoperative thrombosis. Preoperative sur-
gical treatment of varices reduces stasis. Hyper-
coagulability of the blood may be treated with hepa-
rin and the derivatives of coumann. However none
of these methods is absolutely effective. Once throm-
bosis has developed an effort may be made to prevent
embolism by ligating the vein in front of the embolus
by phlebectomy (excising the obliterated segment of
the vein) or by thrombectomy. Villaret, Justin
Besancon, and Bardin use ephedrine for its action on
the sympathetic system, neutral atropine sulphate
as a vagolytic drug and bicarbonate of soda for
alkalinization.

When pulmonary embolism has developed anal-
gesic drugs to quiet the patient's excitement, heart
tonics excluding digitalis and papaverin as a per-
ipheral vasodilator should be given to the patient.
Minor surgical procedures may be used such as in-
filtration of the stellate ganglion and intravenous
and intrapleural injections of novocain.

AUDREY G. MORGAN, M.D.

Redon, H.: *The Surgical Treatment of Pulmonary
Embolism (Traitement chirurgical de l'embolie
pulmonaire)* / *Chir. Par.* 1946 62 267

The idea of opening the pulmonary artery and
extracting an obstructing embolus was conceived
first by Trendelenburg in 1907. Up to 1939 130
cases have been published, 12 of which were success-
ful. Probably the true mortality rate is even higher
since many unsuccessful operations may not have
been published. In view of this high mortality many
surgeons are pessimistic and hesitate to operate at
all; however it should be possible to decrease the
mortality rate under three conditions: precise indi-
cation, perfect organization and impeccable oper-
ative technique.

The time between the occurrence of a massive em-
bolism of the pulmonary artery or one of its main
branches and death is between 30 and 45 minutes on
the average; however this time may frequently be
prolonged to several hours. As some patients survive
without operation the surgeon should be ready for
operation at shortest notice but should wait at the
bedside sometimes for hours and decide on oper-
ating only when the patient begins to die. Per-
fect organization means that a surgeon trained and
experienced in embolotomy should be available on
shortest notice, i.e. within 30 or 25 minutes and
that the equipment should be complete and always
ready for use.

The technique follows more or less the original
concept of Trendelenburg.

A T-shaped incision is made along the left sternal
margin and parallel to the second rib. The second
and third costal cartilages are resected close to the
sternum and the second and third ribs 6 or 8 cm. lat-
erally. The left border of the sternum is resected to
a width of 2 cm. to avoid opening of the pleural cav-
ity. The pericardium is opened at the inferior angle

of the incision. The artery is visualized and opened by a longitudinal incision of 2 cm. and the embolus is extracted by forceps, both main branches of the artery being explored. It is vital to operate at high speed to avoid damage to the nervous centers; the artery should not be clamped for more than 45 seconds.

Two grave errors which have proved fatal in a number of cases must be avoided: one is the accidental opening of the left pleural cavity which may cause death by pleural shock, and the other is not taking the aorta for the pulmonary artery which has been done even by outstanding surgeons.

The postoperative complications include suppurative pericarditis or mediastinitis and damage to the cerebral centers (amaurosis, aphasia). The danger of a second embolism after a longer or shorter interval is always present and should be prevented by ligation of the thrombosed vein. One case is on record in which embolectomy was done successfully twice in the same patient. *WERNER M. SOLMANN, M.D.*

Padgett E. C.: Indications for Determination of the Thickness for Split Skin Grafts. *Am J Surg* 940, 72 653

In skin grafting it is a truism that the advantageous properties of a skin graft are in proportion to the thickness of the graft provided a 'take' can be obtained. Conversely the disadvantageous properties are in proportion to the thinness of the graft except that a 'take' is more assured.

It is obvious then that a skin graft cut at a uniform thickness has positive advantages.

Padgett classifies these sheet skin grafts into four types:

1. **Thiersch.** (Thiersch's original description of his graft as containing only the epithelial layer probably never was nor can be cut; there is always some corium.) This graft is cut from a thickness of about 0.008 (0.2 mm.) to 0.10 of an inch (0.25 mm.)

2. **Superficial and intermediate 'split skin' graft** (Blair *et al.*) This is from one-third to two-thirds of the skin depth in adults usually from 0.012 (0.3 mm.) to 0.016 of an inch (0.4 mm.)

3. **The so-called 'three-quarter thickness' skin graft.** This is cut from 75 to 90 per cent of the skin depth from 0.018 (0.5 mm.) to 0.022 of an inch (0.6 mm.)

4. **The full thickness skin graft.** This includes all skin layers and varies from about 0.030 (0.83 mm.) to 0.038 of an inch (1 mm.)

The following factor has to be considered when the type of skin graft to be used is selected: Is the base granulating or freshly denuded? In addition the location of the recipient area, the age of the patient, the donor area and recipient areas difficult to cover with skin are important considerations.

Lesions for which skin grafts are particularly applicable are the granulating (more or less superficial) relatively nonaseptic areas (whatever their cause may be) and the healed or nearly healed cicatricial contracted lesions due to various causes which

when excised or cross-cut provide an aseptic base. To resurface the former in an adult, a thin skin graft from 0.008 to 0.10 of an inch in thickness is used. To resurface and correct the latter a 'three-quarter thickness' skin graft with certain exceptions, is best.

The author reviews various lesions and states the type of graft best suited for each. These include the unhealed and the healed lesion following severe burns, birthmarks and cavities. He also discusses the making of an artificial vagina, urethra, and eyebrows, and the correction of webbed fingers.

STEPHEN A. ZIEGLER, M.D.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

Hindmarsh J., Mellin G., and Mellin, A. A.: Accidents in Childhood. *Acta chir scand* 946, 94, 483

The authors present an analysis of 5,083 accidental injuries in childhood. The injuries occurred during the period from 1930 to 1940, and were treated in an urban and a rural hospital in Sweden.

The majority of the patients were boys, the number of girls being at times only one half or one-third that of the boys. The accidents had occurred with greater frequency during the first 3 years of life, and the majority of accidents took place during the warmer seasons.

The mortality was low; only 22 of the children died. The children who managed to overcome the first shock seemed to have a distinctly greater capacity for recovery than adults. In the fatal cases death was due to injuries of the cerebrum and abdomen, to burns and (in 1 case) to a fracture. A number of serious accidents in children never reach the hospital.

During early infancy accidents occur in most cases without the co-operation of the child. Examples of such accidents were falls from weighing machines and tables (14 cases) and dropping when moved (6 cases). Cranial injuries resulted in 15 of these 30 children. The remaining 5 children sustained fractures of one of the bones of the lower extremities.

During infancy and in children from 2 to 6 years, burns predominated (313 cases, or 6.2 per cent of the total number of accidents). The causes of burns were as follows: scalding with hot fluids (236 cases), contact with hot metal (33 cases), exposure to chemicals (19 cases), contact with fire (15 cases) and electrical contacts with high voltage current (8 cases).

During the transition to the age of playing, the child enters a period of pronounced curiosity with regard to its surroundings. In 195 cases objects became lodged in the respiratory or digestive tracts. Of the 186 known objects, 147 (79 per cent) were metallic—61 sharp (screws, nails, pins, needles, etc.) and 86 blunt (metal balls, closed safety pins, toy parts and coins). The 39 nonmetallic objects included pieces of glass, celluloid bits, fish bones, toy parts, glass balls, etc. The foreign body was stuck

in the mouth in 2 cases and in the pharynx in 2 cases in the former large objects and in the latter thin, sharp objects. Only in 1 case had the foreign body found its way into the respiratory organs. Generally coins were impacted in the esophagus (16 cases). In 55 children objects were stuck into the nose and in 5 cases in the external auditory canal. Swallowing of corrosive fluids was observed in 19 cases. Nine of the children were 1 year of age and the remainder from 2 to 4 years. Acid was the cause once, while in the remaining 18 cases lye was the injurious agent. In the event of a substance containing lye powder the injuries were generally superficial, but extensive corrosion injuries appeared from strong solutions. There were 57 injuries of intoxication, from the consuming of too easily accessible medicines in 23 cases, chemical washing solutions in 17 cases, diluted noncorrosive acids or alkalis in 8 cases, water color and colored chalks in 6 cases and cigarette ends in 3 cases.

Thirty three children sustained injuries from falling with a stick or similar object in the mouth.

Falls out of bed or perambulators are reported in 115 children, 56 of them infants. Fractures occurred in 55 of these. In 9 cases concussion of the brain was noted. The injuries usually occurred in the upper half of the body, 39 being localized to the upper extremity and 5 to the upper part of the trunk. Only 9 were noted in the lower extremity.

Falls from a window or balcony occurred in 49 children. Fractures often multiple, followed in 32 cases. Nine of the children were 10 to 12 years of age, the rest being 5 years or younger. Falls from a staircase occurred in 150 children. In 57 of these a fracture ensued frequently being a fracture of the clavicle. Concussion of the brain resulted in 38 cases. Injuries due to slamming doors occurred in 21 children. The injuries were localized either to the hand or the leg, they were usually wounds and contusions, and occasionally fractures.

As the result of an adult pulling the arm of a falling child damage to the shoulder or elbow joints may result, represented either by a subluxation of the head of the radius or a distortion in the elbow joint. Injuries of these types occurred in 116 children.

Seventy three children sustained injuries caused by playing in swings and climbing stools. Fractures resulted in 26 cases and concussions of the brain in 8 cases. The remaining children had wounds and contusions.

One hundred and thirty children had injuries from bites—69 insect bites and 39 dog bites. The former do not, in the majority of cases, cause any serious injuries. The effect of the dog bites has been of a more serious kind invariably involving great risk of infection. The latter caused a prolonged and complicated course of healing and ugly scar formation. Dog bites of the head occurred in 16 children, most often in the face and dog bites of the upper extremity occurred in 13 cases, most frequently in the hand. A dog bite was reported in 15 children. 14 of whom received serum.

Thirty-one cases of self inflicted bites of the mouth after falls were noted all of them uncomplicated.

When the child reaches school age gymnastics and sports entered into the cases of accidents. There were 52 accidents occurring during gymnastics, 16 during athletics and 33 during sports. Fractures resulted in 47 cases, contusions in 17 cases, and concussions of the brain in only 4 cases.

As a result of winter sports 177 children were injured the younger while sledding and the older while skiing or skating. At tobogganing 59 children were injured head and leg injuries predominating. Ten fractures of the femur and 15 fractures of the leg occurred. Fifty five children were injured while skating. In 22 of these the injuries were to the arm. Injuries of the leg were common and of the thigh rare. Accidents while skating are a most common cause of concussion of the brain, 15 cases having been noted. Injuries of the extremities often fractures occurred in 40 children as a result of skating accidents.

Traffic accidents account for an important group of childhood injuries. Among pedestrians of all ages who have been subjected to traffic accidents by day light those in the age group of 0 to 10 years suffer the maximum number of accidents, the age group from 10 to 12 years are shown to have the inverse number. Traffic accidents numbered 461 (9.1 per cent of the total number of accidents). After the small number of traffic accidents in infancy a noticeable rise was seen in the 2 year age group which became marked in children between the ages of 3 to 7 years in which group 48.4 per cent of the total number were found. Children in the 6 year age group were the principal sufferers of these accidents. Bicycle accidents were the cause of injury in 242 children followed by motor car accidents in 108 cases. The latter causing the more serious injuries. Of the 461 children 10 traffic accidents, 337 (73.1 per cent) had to be admitted to the hospital for treatment.

Narrow escapes from drowning are common in childhood, but the children do not usually get to a hospital. All but 3 of the children in this group were seriously affected.

In the material from the country hospital, 153 per cent of the children were injured in the performance of household duties.

The authors recommend antitetanus vaccination for children with lacerations in which there is danger of infection or better a combination of diphtheria and antitetanus vaccination of all children. In the present series there were 1,067 such cases.

Fractures occurred in 1,336 instances usually in the upper or lower extremities. Fractures of the skull were found in 118 of the 295 children in whom roentgenograms of the skull were made. Three of these children died. Only 7 of the children had fractures of the base of the skull. A depressed fracture of the roof was noted in 18 children, but only 6 of these children were operated upon. Patients with cranial fractures were treated by rest in bed for at least 1 month while those with simple concussion

were kept in the hospital for 1 week and at home for 1 week.

The mortality from burns was 4.7 per cent, all the deaths occurring in children under 5 years of age. The authors recommend the tannic acid treatment of burns and advise the earlier use of skin grafts.

Foreign bodies in the intestinal tract of children were passed 63 times in from 1 to 22 days. Surgical removal was undertaken in 16 children. Eight coins in the esophagus were removed by the esophagoscope. The remaining 8 objects (1 coin, 3 pins, 2 nails and 2 hair clasps) required removal by opening of the stomach or duodenum. The curves of the duodenum may present difficulties for the passage of foreign bodies.

Prophylactic measures against accidents in childhood are discussed viz. the prevention of burns the isolation of corrosive fluids, medications and poisons in homes, the control of inferior electrical equipment, the sensible choice of toys, the fixing of window catches, gratings and balconies, the supervision of play apparatus, the education of children to traffic, the withholding of bicycles until the age of 10 to 12 years and the institution of social reforms.

LEONARD E. ARNHEIM, M.D.

Perrea, J., Borge P., Parnet, H., and André, J.: *Accidents following Prolonged Compression of the Muscles of the Limbs (Accidents consécutifs à la compression prolongée des masses musculaires des membres)*. *Rev. Méd. et Biol.* 946 73.

In July 1944 the inhabitants of a small French town ran into a tunnel to escape an air bombardment. After a little while the individuals at the back of the tunnel had difficulty in breathing and pushed toward the opening. They were crowded close together and could only move slowly in the darkness. Some of them fell and others stumbled and fell over them until there was a pile of bodies 3 meters high blocking the tunnel for 10 meters. The bodies were so entangled that it was hard to get them out. There were 80 dead and more than 100 wounded.

The authors had occasion to treat 14 of these patients. There were 5 with very severe conditions resulting in death, 1 with a moderately severe condition and 8 with mild conditions. Details of the cases are given. When the patients were brought out of the tunnel where they had been for from 3 to 5 hours their muscles especially those of the legs, were very much swollen and very hard. The skin was livid and cold, with dilated veins. Some of the patients were in a state of shock and most of them said they were in great pain. The urine was scant and very dark. There was evidently a relationship between the continuation of the muscles and the hemoglobinuria or hematuria.

The authors did not know at the time of this English work on the crush syndrome or Bywaters syndrome as it has been named from its first investigator. They concluded that the prolonged compression of the muscles caused capillary hemorrhage and edema. The increase in volume added to the

external violence, brought about complete disintegration of the muscles, which was followed by fibrosis. They believe that the hematonic nephritis and the degeneration of the liver seen in 2 cases were toxic in origin and that the shock also was largely due to intoxication. They do not attempt to explain the labial herpes which occurred in 5 of the cases. English authors advise the application of a tourniquet to the injured limbs and keeping them cold to prevent dissemination of the toxin. The authors gave adrenalinized serum intravenously for the shock and infiltrated the sympathetic nerve with novocain. Transfusion did not seem to be indicated. They used bicarbonated serum for the acidosis to prevent the precipitation of hematin. They used hypertonic glucose solution and insulin in preference to hypertonic salt solution. They performed decapsulation of the kidneys in 1 case, but it was too late; the intoxication was far too advanced. In future they will do early decapsulation.

In the discussion GOSSET said that he thought too much importance had been attributed to intoxication as the cause of these phenomena. They are like those produced when a tourniquet is applied to a limb and ischemia is produced. When the tourniquet is removed the blood rushes in and causes edema, this decreases the volume of circulating blood and explains the initial shock, which is not toxic but circulatory. PERREA replied that it was hard to believe that the total disintegration of muscle in these cases did not result in toxic products which were carried into the body particularly the kidneys and liver.

ANDRÉ G. MOREAU, M.D.

Graham, J. R., and Scott, T. McN.: *Notes on the Treatment of Tetanus*. *New England J. M.* 947, 35 846.

The incidence of tetanus among American forces during World War II was very low, only 1 case had been reported up to February 1, 1945 in troops of the European Theater. In the German Army active immunization with tetanus toxoid was given only to a selected few. Consequently tetanus was frequently encountered in German prisoner casualties treated in American Army hospitals. The authors report 10 cases of tetanus that developed in 3,500 sick and wounded German prisoners treated at an overseas station hospital during the period between September 1944 and March 1945.

Incubation periods ranged from 5 to 22 days, with an average of slightly more than 10 days. Of the 10 patients 4 died all within less than 10 days of the onset of the disease but 3 of the 6 survivors had incubation periods of 10, 8 and 5 days. None of the patients had had adequate prophylaxis, judging from available records. Tetanus toxoid does not benefit a patient who has not been previously immunized for the development of antibodies is too slow to prevent the disease. Fifteen hundred units (American) of antitoxin should be given on the day of wounding and repeated every 7 days, as the passive immunity lasts only from 7 to 14 days. The fact that 9 of the

10 patients had received large doses of chemotherapeutic agents (one patient had been given 1 000 000 units of penicillin and 30 grams of sulfadiazine) prior to the onset of symptoms suggests that these agents will not prevent the disease.

In outlining the signs and symptoms of classic generalized tetanus and of local tetanus the authors emphasize that the most important step in making the diagnosis is to think of the possibility of tetanus.

The treatment of the disease is a major undertaking. The patient should have his own room and special attendants at all times. Usually he will require redébriment of his wound. Radical wound excision eliminates the focus of further toxin formation. Subsequent to the operation all attentions to the patient should be arranged on a schedule at three hour intervals, to minimize the disturbance to his rest. These ministrations will include the giving of sedation and penicillin feeding back massage postural changes. Sufficient antitoxin should be given to neutralize the toxin already produced. In the authors' experience this was 120 000 to 180 000 units of which 20 000 to 40 000 units were given intravenously. Increased metabolic requirements may be met by using a stomach tube (left in place 5 to 6 days) to introduce a daily diet of 3 000 to 3 500 calories containing 120 to 130 grams of protein in 3 500 to 4 000 c.c. of fluid. Sedation must be balanced between the danger of spasms and convulsions resulting from inadequate sedation and the danger of pulmonary complications, the result of over sedation. The authors achieved this balance by using from 4 to 6 c.c. of paraldehyde or 0.2 gm. of sodium amytal orally every 3 hours. Either may be given intravenously for emergency sedation.

Sulfadiazine and penicillin are effective in preventing wound infection and pulmonary infection subsequent to a tetanosis which was an almost universal complication in the authors' cases. Their treatment of tetanosis included voluntary coughing frequent changes of position postural drainage, carbon dioxide-oxygen inhalations, and slaps on the back to loosen mucus plugs. To avoid excretory complications they advocate the routine use of mineral oil as a prophylaxis against fecal impaction and the placing of indwelling catheters to prevent urinary retention secondary to sphincter spasm.

B F LOUWERY M D

De Lavergne V, Helly J and Faivre, G: The Ineffectiveness of Local Surgical Treatment in Manifest Tetanus (De l'Inutilité du traitement chirurgical local dans le tétanos déclaré). *Presse méd* 1946, 54 602

Larrey first recommended amputation of the injured limb in manifest tetanus, and at the meeting of the Surgical Society in 1928 the physicians and surgeons present were almost unanimous in their opinion that surgery should be practiced. Small series of statistics were presented to prove this point, but it is well known that there are many sources of error in small series of statistics.

The statistics of the authors' own clinic show that the results are rather better in nonoperative than in operative cases and the difference is still more apparent in cases of postabortion tetanus. The argument for local operation was that the spores and bacilli were removed and this prevented the formation of toxin. However it has been shown that the bacilli do not remain localized at the portal of entry. They have been found on compresses placed on the operative wound which shows that they exist in tissues at a considerable distance from the portal of entry.

Surgery has never been recommended in diphtheria. It is true that antitoxin is more effective in diphtheria than in tetanus. This is because the angina of diphtheria develops while the toxin is still free and indicates merely the portal of entry while trismus in tetanus does not develop until the toxin has been fixed at a distance. There are no clinical symptoms in tetanus at a stage corresponding to the angina of diphtheria. In tetanus antitoxin should be given in addition to antitoxic serum for while the former does not destroy tetanus toxin it protects the patient from further injury by destroying the remaining spores and bacilli. AUDREY G MORGAN M D

Sulzmann M: Concerning the Mechanism of Infection in Chronic Recurrent Staphylococcal Diseases. A Special Clinical Bacteriological Investigation of Furunculosis and Its Complications (Ueber den Infektionsmechanismus bei chronisch rezidivierendem Staphylokokkenkrankheiten. Eine klinisch bakteriologische Untersuchung speziell ueber die Furunkulose und ihre Komplikationen). *Zeitschr. f. Bakt. u. Abw.* 1946 94 291

Chronic staphylococcal skin infections have been more frequent in Finland during the war years. In order to gain a better understanding of these cases the mechanism of infection was investigated in its bacteriological and clinical aspects. Of especial interest to the author was the problem of pathogenicity of various strains of staphylococci. Likewise he was interested in determining whether recurrent infections in the same individual represented reinfection with the same bacterial strain or whether the recurrences represented new infection with other strains. The following criteria of pathogenicity were used: pigment formation, production of hemolysin, formation of plasma coagulase and destruction of mannitol.

One hundred healthy patients were studied. Sixty-six staphylococcal strains were recovered from the skin and 64 strains from the nasal secretions. Specimens were taken from pus in 150 acute infections. Twenty-one per cent of the skin strains were pathogenic according to 2 of 3 or 3 of 4 criteria. Similarly 46 per cent of those from the nasal secretions and 93 per cent from pus were pathogenic. None of the criteria of pathogenicity were found among 57 per cent of the skin organisms, 41 per cent of the nasal staphylococci and 4 per cent of the organisms taken from pus. The remainder were not definitely in either category.

Sixty patients with relapsing staphyloiderma were studied: 47 were males and 13 females. Sixty per cent of the cases occurred in apparently healthy individuals and consisted of typical recurrent furunculosis. The other 40 per cent were associated with fairly obvious predisposing factors such as diabetes pseudodibetes, malnutrition or local disturbances. These included such cases as multiple furunculosis, carbuncles, bullous or impetiginous staphyloiderma and similar disorders with defective healing and a tendency to become chronic.

In vitro tests were performed in staphylococcal infections of long standing. The organisms isolated seemed to be somewhat more pathogenic than those taken from acute pyogenic infections. Cultures taken from several lesions at different times in multiple furunculosis showed only one strain in one and the same patient. In about half of the patients with furuncles the same organism was present in the nose and on healthy skin suggesting that the skin and mucous membrane were the sources of reinfection. Many patients with obvious low resistance were infected with strains which seemed relatively non pathogenic in vitro.

In conclusion the author advises surgical incision of furuncles and radical excision of carbuncles except on the face. To cope with recurrences he suggests careful asepsis in handling, local applications of antiseptics to the skin and chemotherapy. He is uncertain about the value of polyvalent vaccine. Obvious causes of decreased general resistance such as diabetes or cachexia are corrected.

THEODORE B. MARSHALL, M.D.

Govan, A. D. T.: An Account of the Pathology of Some Cases of Clostridium Welchii Infection. *J. Path. Bact. Lond.* 1946 58 4 3.

The first portion of the present article is concerned with a description of the local pathological changes in gas gangrene based on 120 muscle biopsies from service casualties. Immediately adjacent to the wound surface is a zone of necrosis involving all structural elements considered by the author to be due to the original injury. Peripheral to this zone is an area of marked edema in which the muscle fibers are widely separated from each other; there is beginning loss of muscle striation, and degenerative changes in the nuclei are moderately advanced. This zone merges into a more peripheral one in which the edema is accompanied by intense vascular congestion and the muscle shows fewer evidences of degenerative change. Extreme vasodilatation and extensive hemorrhage is present, and many vessels are thrombosed. The author stresses the significance of the thrombotic phenomenon in this zone as he believes that this is a primary cause for the characteristic necrotic changes of Clostridium welchii infection.

The second portion of the article deals with material drawn from post mortem examinations in 3 cases of severe Clostridium welchii infection. In all 3 of the cases diffuse fat emboli were found to form a significant part of the post mortem picture. Fat emboli

were prominent in the lungs and in the central nervous system. fat emboli were demonstrated in the optic nerves of 1 patient in whom blindness had appeared before death.

Experimental work is quoted in which the injection of Clostridium welchii toxin into the thigh muscles of guinea pigs and rabbits invariably gave rise to extensive pulmonary fat emboli. The possible mechanisms to explain this phenomenon are discussed.

F. J. LEECHMAN, M.D.

ANESTHESIA

Leigh, M. D. and Belton, M. K.: Premedication in Infants and Children. *Anesthesiology* 1946, 7 611.

The advantages gained by premedication are important in infants and children as well as in adults. In addition, a most important factor in children is the curbing of a rapid exhaustive respiratory rate. This increased respiratory rate, sometimes over 100 per minute, is found especially in the unmedicated infant who receives ether without due attention having been given to the elimination of carbon dioxide.

The postoperative nausea and vomiting frequently seen following preoperative medication with opiates may be offset to a large extent by adding one of the barbiturates. They are also most effective because they allay apprehension and prevent early convulsions.

There is a tremendous advantage in preventing the secretions in the respiratory tract by the use of drugs of the belladonna group. Scopolamine is more effective than atropine in this respect and has a longer duration of action. Atropine, on the other hand, is thought to reduce the dangers from vagal reflexes on the heart. A table is given in the original article showing the dosages of morphine and scopolamine or atropine for patients of a month of age and upward. This table gauges the dosage not only by the age of the child but also by the weight which may cause the dosage to vary considerably.

A warning is given regarding the measurement of the small doses of drugs. They should be dissolved in several cubic centimeters of sterile distilled water and thoroughly mixed so that the calculated dose can be more accurately administered.

Since any injection with a needle is painful it is best to give attention to details such as not allowing the child to see the needle, using sharp needles without barbs, allowing the alcohol to dry on the skin before injection, and by firmly pinching a generous part of the skin and subcutaneous tissues.

Morphine and scopolamine are given about an hour before operation, morphine and atropine one-half hour and atropine alone one-half hour before operation. Barbiturates such as nembutal and secobarbital are given an hour before operation.

MARY KARP, M.D.

Clement, F. W.: Nitrous Oxide-Oxygen Anesthesia. *Anesthesiology* 1946 7 66.

The familiar terms, anoxia, anoxemia, and asphyxia are often confused or loosely applied. The

occurrence of anoxia is not confined to the administration of nitrous oxide alone but may occur with any and all of the anesthetic agents. For many years the oxygen exclusion theory was accepted to explain the action of nitrous oxide in producing anesthesia. However every anesthesiologist of experience has encountered cases in which the oxygen percentage in the nitrous oxide-oxygen mixture could be increased considerably above 30 per cent (which is roughly the normal air content of oxygen) and still maintain adequate anesthesia. Today the commonly accepted theory is that nitrous oxide itself possesses weak anesthetic properties.

All anesthesiologists should be familiar with the possible dangers of nitrous oxide-oxygen anesthesia. Nevertheless such dangers arise not from the action of gas itself but from its maladministration. No anesthetic is safer than the one who gives it. The effects of anoxia have been evident after all types of anesthesia but the anoxia state may be more readily produced with nitrous oxide-oxygen anesthesia than with other anesthetic agents and the margin of safety is narrow.

Respiration is by far the most important sign during nitrous oxide-oxygen anesthesia. The patient is in no danger as long as he is breathing efficiently but if *i.e.*, machine like respirations inspiration and expiration about equal the rate somewhat faster than normal and continuous or uninterrupted with adequate volume. The greatest single hazard during nitrous oxide-oxygen anesthesia is the failure once anesthesia has been established to effect a gradual increase in the oxygen percentage of the mixture. The need for oxygen is usually very apparent because of the muscular responses of the patient. However the weak anemic, or debilitated patient does not necessarily show musculo spasm during deep anesthesia in fact flaccidity may occur. In such cases the danger signals are largely respiratory.

Once the desired depth of anesthesia is attained the oxygen concentration should be increased 1 per cent at a time while the effect of each increase on the level of anesthesia is noted. Failure to increase the oxygen supply as anesthesia progresses may well lead to fatal or near fatal degrees of anoxia.

During nitrous oxide-oxygen anesthesia the application of a simple and accurate test will reveal whether or not anesthesia is being maintained at a depressing level. This test is based upon the fact that whenever a patient in need of oxygen is given an abrupt and abundant supply slowing of the respiratory rate or even temporary cessation of breathing occurs.

The duration of the apneic period is in direct ratio to the degree of oxygen deficiency. If at any time the anesthesiologist is in doubt regarding the depth of anesthesia he should administer one or two breaths of 100 per cent oxygen and observe the effect (if any) on the respiration.

The use of oxygen is not mandatory in the Army Air Forces until above the 10,000 foot level (14.25 per cent oxygen). Surely a patient premedicated

asleep and quiet in anesthesia can tolerate a comparable decrease of oxygen reduction.

Induction with 100 per cent nitrous oxide is advised for normal risk patients. For subnormal risk patients and children a mixture of oxygen nitrous oxide is advocated in order to decrease the possibility of inadvertent rapid production of the profound plane. No other anesthetic agent equals it in speed of absorption and elimination from the body. Also it is free from the hazard of explosion.

MARY KARP M.D.
D Errico G. Intravenous Anesthesia in Man (La narcose endovenosa nell uomo) *Gior ital chir* 1946 2 399

The following advantages of intravenous anesthesia have been pointed out by several writers:

- 1 It is possible to induce anesthesia with barbiturates in persons in whom superficial veins cannot be located.

- 2 Repeated doses of anesthesia may be administered without the need of a special apparatus to keep the needle in place.

- 3 The needle remains in proper position in spite of agitation of the patient.

- 4 The same needle may be used for transfusions of blood or plasma or for the administration of saline or glucose solution.

- 5 The danger of a venous thrombosis is avoided.

- 6 The surgeon has the opportunity to supervise help because the needle is located in a sterile easily accessible field.

Endosteal anesthesia has been employed by the author in 19 cases. In 3 instances complications arose in 1 case a subcutaneous aseptic abscess developed in another peritonitis and osteoperitonitis of the sternum appeared following the anesthesia but subsided spontaneously within a few days and in the third a grave osteomyelitis of the sternum was attributable to the mode of administration of the anesthetic. The patient in the last case a 46 year old man with syphilis recovered after incision and drainage.

A 2.5 per cent solution of sodium pentothal was used for anesthesia. Preoperatively morphine and atropine were given. In all instances the manubrium sterni was used as the site of injection and the usual precautions with regard to the preparation of a sterile field were taken. An average from 5 to 10 c.c. of the anesthetic solution were injected within 2 to 10 minutes additional amounts being given from time to time according to the condition of the patient.

An infection following sternal puncture for anesthetic purposes may be caused by the introduction of pathogenic micro-organisms from the outside or it may be attributable to bacteria which reach the sternum from the blood stream.

The occurrence of 3 complications in a group of 19 patients induces the author to condemn the sternal administration of an anesthetic.

JOSEPH K. NARAT M.D.

Bishop H. F.: *Operating Room Deaths. Anesthesiology* 946 7 65

During the last few years the trend has been toward a full and impartial report on operating room deaths—a progressive step which is believed to be in keeping with the true scientific spirit.

In the line of progress, the operating room should be made a safer place for the patient to enter. Anesthesia societies have recently shown interest in the creation of anesthesia study commissions whose purpose it is to sift the facts impartially concerning operating room mortality.

In most instances death under anesthesia is the result of failure of circulation or respiration. Evidence bearing on the actual mechanism of death is frequently inconclusive. Goggio has attempted to distinguish between those cases in which the heart ceases to function because of asphyxia and those cases in which the heart stops in asystole or ventricular fibrillation.

Anesthetic drugs have been involved in 20 per cent of the deaths (caused by drugs) which have been reported to the medical examiner in the Boston area. These deaths under anesthesia were classified into the following subgroups: (1) aspirated vomitus (2) serious preexisting disease of an inflammatory or degenerative nature (3) sudden deaths on a neurogenic basis (4) delayed deaths (5) deaths without known cause.

Pressure over the carotid sinus should be avoided during anesthesia. A fatality may result if pressure is applied in this region of the neck on individuals who have a hyperactive sinus reflex which has been sensitized by certain anesthetic drugs such as nitrous oxide and morphine. Coronary occlusion may account for as high as 20 per cent of the sudden deaths occurring in adults undergoing operation.

The author presents a report on 6 deaths which occurred in the operating rooms of two hospitals with which he has been associated during the past 4 years. A total of 20,021 anesthetics have been administered during that time.

Case 1: A patient with suspected brain tumor was given avertin for an exploratory craniotomy. Respirations ceased before operation was started and after 30 hours in a respirator heart action ceased. The following management is suggested in such cases: trephine openings are made through the skull the day before operation. A ventriculogram is made on the morning of operation. The patient receives scopolamine premedication only. Just before the induction

of anesthesia the surgeon is asked to insert a brain cannula into each ventricle to reduce any increased pressure that may be present. In this way anesthesia induction is not commenced with an existing elevated pressure.

Case 2: A baby 4 days of age died at the completion of an operation for congenital atresia of the esophagus. No anesthesia was used although oxygen was given during operation. It was believed that the amount of blood loss might have accounted for the shock and death of the infant. For babies, one should cut down on an ankle vein and tie an 18 gm intravenous cannula in place before operation.

Case 3: Death occurred suddenly and unexpectedly in a 27 year old asthmatic patient while undergoing therapeutic stellate ganglion block. Death in this case might be explained by the observation of Cromer and Ivy who following a series of experiments on dogs in 1933 reported that bilateral resection of the stellate ganglia sensitized the respiratory center to impulses rising in the vagus nerve and caused respiratory paralysis.

Case 4: The death of a 76 year old patient was attributed to fatal pulmonary embolism during manipulation of a hip fracture under anesthesia. Six similar deaths during manipulation have been reported to the author. It is difficult to understand how the type of anesthesia could have changed the outcome in these cases. On numerous occasions during manipulation for hip fractures (Leadbetter no. 1) the author has encountered sudden circulatory changes which were transient and were vaguely passed by as some type of reflex response.

Case 5: A 2½ year old child undergoing revision of a cleft palate under ether insufflation anesthesia died 30 minutes after the start of anesthesia. It was generally agreed that asphyxia was the cause of death. There has existed some opposition to the use of endotracheal tubes in infants and small children, but most writers are definitely in favor of them. It was believed that an endotracheal tube might have prevented this death.

Case 6: An 11 months old baby died during the repair of a harelip. It was considered that death resulted from asphyxia, caused by an error in the application of an endotracheal tube which was too long, and entered the right main bronchus.

Tragedies of this kind can serve some useful purpose if an exhaustive study is carried out on all operating room deaths.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Kooperstein, S. I. and Bass, H. E. A Pulmonary Reaction following Intrabronchial Instillation of Lipiodol in Bronchial Asthma *Am J Roentg* 1946, 56 569.

The authors report that in a study of 40 cases of bronchial asthma including bronchograms as a part of the clinical investigation 3 patients developed febrile illness with roentgen evidence of pulmonary infiltration. The lipiodol used in these cases was the commercial product consisting of iodized poppy seed oil (40 per cent) Butyn sulfate 2 per cent was introduced intranasally, and anesthesia of the bronchial tree was attained by the gravity method. Lipiodol was swallowed to visualize both lower lobes and the right middle lobe.

Two of the patients developed an acute episode characterized by a rise in temperature, cough, expectoration, and malaise at the end of 9 and 12 days respectively. The third developed an acute pulmonary episode characterized by chilly sensations, malaise, subcostal pain, and cough. Roentgenograms of all 3 patients revealed bilateral basal densities which suggested the presence of pneumonia in the areas of the distribution of the lipiodol except for an additional shadow of increased density in the upper right lung field of one of the patients. All of the cases showed an increase in the total white blood count and polymorphonuclear neutrophils. Marked eosinophilia paralleled the course of the acute illness in 2 of the cases and was absent in the other. Two of the patients developed an urticarial eruption one at the onset of the illness and the other 2 days after the bronchogram was taken.

Sensitivity tests were done on the 3 patients and 10 control cases with lipiodol, diodrast, poppy seed oil and butyn sulfate (2%) respectively. All of the controls failed to react. The 3 patients reacted in varying degrees to diodrast and 5 of them reacted to scratch tests of lipiodol. None of the 3 reacted to the tests with poppy seed oil or butyn sulfate (2%).

The authors conclude that the 3 cases of bilateral pneumonia which followed lipiodol bronchograms offer evidence of having been caused by the lipiodol.

FRANK L. HUSSEY, M.D.

Schilling, J. A.: Perforation of a Duodenal Ulcer during Roentgen Examination. *Surgery* 1946 20 730.

Perforation of a duodenal ulcer during fluoroscopic examination is fortunately very unusual. Fifty-seven cases have been reported that occurred either during or immediately following a barium study. The author's case falls in the first group.

During the routine fluoroscopic examination of a 71 year old white male who had had two large fatty stools 3 days previously the barium suspension was

Fig. 1 (Schilling). Flat abdominal x-ray film taken at time of perforation. Note barium concentrations in the right and left lower quadrants. No barium is present deep in the pelvis or in the right subphrenic space.

seen to escape from the duodenal bulb and flow both to the right and the left and promptly outline the right lower boundary of the peritoneal cavity.

Following laparotomy a 1.5 cm perforation was found on the anterior portion of the duodenum. A large amount of black watery fluid was present, but the extravasated barium was fixed in small clumps and flecks by a fibrinous exudate. These flecks were distributed over all of the free peritoneal surface of the intestines and abdominal wall. Removal of the barium was impossible.

The patient's postoperative course was rather stormy. During the first 3 weeks there was considerable abdominal pain and diarrhea, and a large tender pelvic mass developed which subsided slowly. During the second month an eosinophilia averaging 23.5 per cent with a white blood cell count of from 10,000 to 20,000 developed, although the patient was essentially asymptomatic. A check-up examination after 6 months revealed essentially normal findings.

This case illustrates the route of spread of intra-peritoneal effusions from the right subhepatic space. On the right side the effusion passes first to the right

infracolic space then across the ascending colon and caecum to the right lumbar gutter or paracolic groove then to the right subphrenic space. On the left side the subphrenic space is involved directly from the infracolic space and to a lesser extent from the left paracolic groove and both right and left subhepatic spaces.

Figure 1 taken at the time of perforation illustrates both the avenues of peritoneal spread and the rapid and relative diffuse nature of the spread. Films taken 10 days later showed rather large amounts of barium in the right subphrenic space and in the deep pelvis. One hundred and thirty nine days after the perforation there had been relatively little change in the distribution of the opaque material.

The microscopic distribution of intraperitoneally injected barium sulfate was studied in 3 dogs. Films made following the injection revealed the same rapid and diffuse spread of the solution and relatively little change in the distribution after the first few hours. Postmortem examination revealed the barium to be distributed throughout the entire peritoneal cavity. There were dense adhesions at the sites of the barium deposits, especially between the bowel loops and the parietal peritoneum. The mesenteric nodes were enlarged and contained barium. The lymphatics of the omentum and mesentery in 1 instance were clearly outlined with streaks of barium. Some of the thoracic nodes near the internal mammary vessels contained large quantities of barium. These nodes were observed on the antemortem roentgenograms. Microscopically only moderate numbers of giant cells were present. There was round cell infiltration and fibrous encapsulation of small amounts of barium. In the omentum all of the barium was in either large single or multiple confluent macrophages.

R. B. Lewis, M.D.

Dann D. S., and Koritschoner R.: A Clinical Study of Normal and Pathologic Motor Activity of the Gall Bladder. Preliminary Report. *Radiology* 94:6 47 494.

The motor activity of the gall bladder was studied in 21 healthy apparently normal individuals.

Oral administration of sodium tetracosylphthalate resulted in good visualization in 16 cases, fair visualization in 3 cases, medium visualization in 1 case, and an absence of shadow on repeated examinations in 3 cases. One woman presenting good visualization did not return for postcibal films. The remaining 18 individuals pursued their normal daily activities and maintained their customary dietary habits following the roentgen demonstration of the gall bladder. Films were made over the gall bladder region 1 hour after each meal until the shadow of the dye completely disappeared.

Although a wide range in emptying rate normal was observed during the first 24 hours, there was no difference in the rate of emptying in the cases with fair and medium visualization compared to that in the cases with good visualization. One gall bladder required 48 hours for complete emptying although the

meals were thought to be ample in fat, while another emptied completely after the first meal which contained practically no fat. In 2 cases there was no contraction following the first meal which was adequate in fat but the gall bladder responded satisfactorily after a second meal which was variable in its fat content.

Since the response of the gall bladder in these apparently normal individuals was so varied following meals of different fat content, the authors question the significance of the so-called poorly functioning gall bladder "i.e. the normally visualized gall bladder with delayed or slow contraction following a meal containing fat."

R. B. Lewis, M.D.

Perkins A.: Roentgen Diagnosis of Diseases of the Neck of the Bladder. *Am J Roentg* 94:6, 51-489.

The author presents a discussion of the anatomical conditions which cause the so-called disease of the bladder neck and their known syndrome.

The diagnosis of many of these conditions can be made by urethrocytography. Roentgenograms are made at the termination of filling of the urethra with a suspension of 15 to 20 c.c. of barium (base, barium sulfate), an empty bladder having been previously filled with 60 to 80 c.c. of this opaque material. Oblique and anteroposterior films are taken. Three of the roentgenological images obtained correspond to anatomical conditions.

1. Image of the plane neck without protruding borders in both the profile and anteroposterior roentgenograms. It represents a hypoplasia of the sphincter itself. It corresponds to both congenital and acquired atrophy and to sclerosis of the neck. The differentiation between them can only be made by clinical examination in association with some roentgen characteristics of the prostatic urethra.

(a) In congenital atrophy the prostatic urethra is short or slender and much elongated. Sometimes the colliculus seminalis is hypertrophied.

(b) In acquired atrophy the internal opening of the urethra is changed, but the prostatic urethra may keep its proportionate dimensions (constriction of the neck, partial or total resection). In the atrophy of senile involution with reduction of the size of the prostate, obviously the prostatic urethra is shortened.

(c) In sclerosis of the bladder neck, shortening generally occurs because of the inflammatory retraction of the prostate gland.

The image is identical in the profile and anteroposterior roentgenograms. It shows a punctate smooth neck in the fundus of the bladder which does not change under anesthesia (operative verification).

2. Fish-mouth image. This represents exaggerated growth of the borders into the bladder cavity and corresponds to an exaggerated tonus of the sphincter. The image corresponds also to what is seen in the neck when the bladder is opened. But under local anesthesia more than under spinal or general anesthesia, the sphincter relaxes and the protrusion disappears. It is therefore a transitory image and exists only when there are attacks of hypertonia of the sphincter. In certain

issues of the medulla the hypertonia becomes permanent and in that case the image persists and is not changed by any kind of anesthesia.

3 Image of hypertrophy of the trigonal muscle. Here the tissue which corresponds to the trigonal muscle is increased and tends to invade the bladder and deviates the internal opening of the urethra so that it projects forward. As it is a progressive condition in the early stages, the prostatic urethra is not changed and the muscle protrusion is not perceptible.

The roentgen image faithfully reproduces these appearances but only in the profile roentgenogram. The posterior border of the internal opening of the urethra grows forward and becomes superimposed on the anterior border even forming a sort of valvular tongue. In the anteroposterior roentgenogram taken in the advanced stages, the image may resemble that of adenoma of the median lobe in the beginning of its growth. When the hypertrophy of the median lobe coincides with hypertrophy of the trigonal muscle the image does not show anything characteristic, except the projection of the adenoma itself.

FRANK L. HURLEY M.D.

Soole, A. B., Jr.: Ossification of the Coracoclavicular Ligament following Dislocation of the Acromioclavicular Articulation. *Am J Roentg* 1946 56 667

Ossification of the coracoclavicular ligament following partial or complete avulsion of the ligament incidental to dislocation of the acromioclavicular articulation is apparently a common sequela of a relatively common type of injury.

In the series of 18 cases reported in this article, 14 of the patients with dislocation of the acromioclavicular articulation subsequently developed osseous deposits in the coracoclavicular ligament. Dislocations of this joint are described as incomplete or complete, the latter term being applied when the coracoclavicular ligament is severed. In all dislocations there is tearing of the articular capsule and usually of the superior and inferior acromioclavicular ligaments, or both.

X-ray examinations of both shoulders in injuries to the acromioclavicular joints should be made with the patient in the upright position and a 20 pound weight in each of his hands. Widening of the injured joint and elevation of the acromial end of the clavicle is demonstrated in this way.

Ossification of the coracoclavicular ligament has been observed as early as 22 days following injury. It usually appears as a group of amorphous, cloudy areas of light density below the outer third of the clavicle, frequently near the conoid tubercle and process. These areas increase rapidly in size and density and within several weeks take on definite characteristics of bone being laid down in strands and spicules corresponding more or less to the lines of the fibrous strands of the conoid and trapezoid fascicle. While

the bone frequently becomes attached firmly to the clavicle above, it approaches, but rarely becomes continuous with, the coracoid process below. The process of ossification appears to be progressive for a period of about 8 or 10 weeks and then shows no perceptible change on subsequent examinations.

If ossification had not appeared within 6 weeks following injury it was not noted subsequently. The production or absence of ossification appeared to have no relationship to motion in this series of cases because in nearly all of the cases the shoulders were immobilized very shortly after injury.

Post traumatic ossification of the coracoclavicular ligament is a common sequela of avulsion of the ligament associated with dislocation of the acromioclavicular articulation. The ossification appears between 3 and 6 weeks following the injury and becomes complete about 8 or 10 weeks following the injury. The ossification does not appear to contribute to the disability of the patients.

FRANK L. HURLEY M.D.

Young, B. R.: The Roentgen Treatment of Bursitis of the Shoulder. *Am J Roentg* 1946 56 636

During a 6 year period 87 patients with bursitis were treated by radiation therapy. Patients were divided into three categories according to the duration of their symptoms. Symptomatology of less than 1 week's duration was classified as acute. Pain and disability lasting between 1 and 8 weeks were classified as subacute. Symptoms enduring more than 2 months were considered chronic.

In all three groups females outnumbered the males by 2 to 1. In the acute stage the diagnosis was made on the basis of clinical findings of pain and limitation of motion as well as local signs of heat and swelling. The diagnosis was more difficult in the subacute and chronic stages. Roentgen examination was necessary to establish or rule out calcification of the soft tissue or any other demonstrable pathology. The presence of calcification in itself was not too important. The history of the disease and the clinical findings were much more important for the evaluation of the activity of the disease. Calcium deposits were present in 43 per cent of the patients.

Roentgen therapy in the acute stage consisted of three treatments of 150 r in air. Sometimes a fourth treatment was needed. Subacute cases were treated twice weekly for a total dose of 600 r. Therapy in the chronic cases varied. Twenty-nine were treated twice weekly for 2 weeks, 11 received weekly treatments for 8 weeks and 8 were treated on 3 consecutive days with an additional treatment a week later.

Results of roentgen therapy in the treatment of bursitis of the shoulder indicate that this treatment is valuable in the acute and subacute stages. All but 2 patients in the acute stage were relieved of pain in a week or less. Two-thirds of the patients in the subacute stage reported relief from pain in 2 weeks or less. Only one third of the patients in the chronic stage reported relief from pain. A second series of radiation therapy was never given to the patients with recalcitrant chronic bursitis.

MAURICE D. SACHS M.D.

MISCELLANEOUS

Buchta, J. W.: Radioactive Isotopes. *West J Surg* 1946 54 467

The author briefly describes some of the basic physics of radioactive isotopes.

The atom of each element is composed of three fundamental particles: the electron, the proton, and the neutron. The electron is the smallest particle of negative electricity; its mass is about $1/2000$ of that of the proton and neutron. The proton carries a positive charge equal in magnitude to that of the electron; the neutron has no electric charge. The mass of the proton is practically the same as that of the neutron.

The central core or nucleus of the atom contains definite numbers of protons and neutrons. Around the nucleus revolve electrons, their number always being equal to the number of protons in the nucleus. Thus the hydrogen, which is the simplest atom, has a nucleus containing a single proton and there is a single electron revolving around the nucleus. The helium has a nucleus composed of two protons and two neutrons and there are two orbital electrons. The iodine has a nucleus of 53 protons and 74 neutrons, and so forth.

The "atomic weight" of an element is approximately equal to the total number of protons and neutrons contained within the nucleus, whereas the total number of the electrons (and hence also of the protons) indicates the atomic number of the element. Thus hydrogen has an atomic weight of 1 and an atomic number of 1 (H); helium has an atomic weight of 4 and an atomic number of 2 (He); iodine has an atomic weight of 127 and an atomic number of 53 (I^{53}). The chemical properties of the elements are determined by the atomic number, that is by the number and orbital arrangement of the electrons revolving around the nucleus and are quite independent of the nuclear structure. Therefore, it is possible for an element to have varieties with the same atomic number but different atomic weights. These varieties are called isotopes. For example, the oxygen with 8 orbital electrons, or an atomic number of 8, may have a nucleus of 8 protons and 8 neutrons (O^{16}), a nucleus of 8 protons and 9 neutrons (O^{17}) or a nucleus of 8 protons and 10 neutrons

(O^{18}). Most of the elements have stable isotopes; it has 10. Since the isotopes of a given element have identical chemical behavior, they can be separated only by some other method than ordinary chemical process as, for example, by diffusion or electrolysis.

Radioactivity involves disintegration of the nucleus which may occur naturally in some of the heavy elements or may be induced artificially by nuclear transformation in every element of the periodic table.

The rate of disintegration cannot be influenced. The half lives of the radioactive products vary from a fraction of a second to millions of years. The uranium has the longest half life of all and is most abundant.

The number of radioactive isotopes already exceeds 300. All the elements of the periodic table have at least one radioactive isotope, and some have more than one-half dozen.

During the disintegration process of a radioactive isotope, electrons or (rarely) positrons are emitted, not infrequently accompanied with gamma rays.

An extremely sensitive apparatus for the detection of radioactivity is the Geiger counter which registers every single ionizing particle in the form of a "click." The number of clicks per minute is an indicator within certain limits of the strength of the radioactivity. If one drinks radioactivated salt water the Geiger counter will detect the presence of radioactive sodium in the hand within a quarter of an hour. A similar procedure can be used for tracing a radioactive substance in any part of the body.

The many possibilities of tracer studies are immediately obvious. Reports have already been published on the usefulness of more than a dozen tracers in all types of biologic experiments.

Up to the present, radioactive isotopes have been produced in comparatively small quantities through bombardment with the cyclotron or with the aid of intensive sources of natural radioactive substances. Now the use of the uranium pile, which yields enormous numbers of neutrons permitting a very efficient nuclear transmutation, has considerably increased the availability of nearly every radioactive isotope. Another valuable supply is obtained from the contamination fission products of the atomic bomb pile.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Andres W. A., and Browne, J. S. L.: Ascorbic Acid Metabolism after Trauma. *Canad M Ass J* 1946 55 435

The authors summarize briefly what has been known about ascorbic acid wound healing and callus formation and then report their own studies which were done on patients with a normal vitamin C intake and not, as most previous studies, on patients with vitamin C deficiency.

They find that patients after trauma (fractures, burns) require considerably more ascorbic acid in order to become saturated with it than do normal persons. Their needs resemble those of patients with experimentally induced scurvy. However, while in the scorbutic individuals such increased vitamin C intake is necessary to promote wound healing, no significant clinical effect of saturation doses of ascorbic acid is found in traumatized patients with an initially approximately normal vitamin C status.

HEINRICH LAMM, M D

Hoet, P. and Hugnier, J.: The Probable Role of Reflex Capillary Stasis in General Pathology (Le rôle probable de la stase capillaire réflexe en pathologie générale). *J chir., Par* 1946 63 184

The authors contend that all trauma provokes reactions which are generally admitted to be of a reflex nature and that local reflex reaction is the constant means by which the organism reacts to aggression of any sort at any site.

Following trauma a local reflex capillary stasis occurs, with increased arterial pulsations proximal to the site of trauma comparable to those which occur proximal to any arterial obstruction. Capillary stasis rapidly induces serous exudation which is manifested by edema, blisters, and joint effusion. If the stasis is intense local diapedesis and even hemorrhage may occur. Sympathectomy by producing active hyperemia, relieves the local capillary stasis.

Assuming that diffusion of reflexes is a common phenomenon the authors suggest that the general reactions to trauma such as shock may represent in effect a diffusion or spread of the local reflexes to produce a peripheral vasomotor stasis.

EDWARD W. GIBBS, M D

Holabec, H.: An Improved Intravenous Treatment of Intestinal Occlusion. An Experimental Study (Úprava vnitřního proštění a účinná nepřechodnosti. Experimentální studie.) *Lah listy* 1946, 1 106.

The rapid infusion of large quantities of physiologic saline solution has been observed to result in degeneration of the cardiac muscle and kidney par-

enchyma eventuating at times in circulatory failure and even in anuria. Likewise Ringer's solution leads at times to edema.

The author in studying the method of injecting plasma with the physiologic saline solution as recommended by Gendel and Fine (*Ann Surg* 1940 111 248) employs the exact technique of the American authors. However a closer study of blood conditions during the experiment convinces him that the early losses in water and electrolytes, and the later loss of plasma from the blood in experimental sufflation distention of an isolated segment of small bowel, together with reduction in the albumin globulin ratio denotes a change in the colloid conditions in the blood plasma, rather than the previous explanations on the basis of humoral changes in the blood.

The coincidental injection of plasma and physiologic saline solution permits of the use of smaller quantities of the latter and is thus regarded as a definite improvement in the treatment of ileus.

JOHN W. BRIDGEMAN, M D

McKittrick, L. S.: Recent Advances in the Care of Surgical Complications of Diabetes Mellitus. *N England J M.*, 1946 235 929

The general safety of all patients undergoing surgical procedures has been increased immeasurably during the past few years, and although diabetic patients necessitate special attention to their local and general surgical conditions as well as their diabetes mellitus recent experience has shown that their metabolic disorder is no contraindication to any surgical procedure. Surgical emergencies should be avoided as much as possible in order to insure the safest possible convalescence. This discussion of diabetic surgery deals with problems involved in operations accounting for about two-thirds of the surgery performed on diabetics at the New England Deaconess Hospital. These operations were necessary for infections of the skin and subcutaneous tissues, especially carbuncles, and for gangrene and infection of the lower extremities.

Among 95 patients operated on for carbuncles between 1928 and 1941 there were 7 deaths. This, however, gives little concept of the seriousness of this condition to the diabetic. The recently instituted treatment of carbuncles with penicillin (from 100,000 to 300,000 units daily for from 7 to 10 days) has been most gratifying. This results in the disappearance of large early carbuncles or the change of advanced infections to small painless fluctuant areas which heal promptly after local incision. Penicillin has reduced materially the morbidity, mortality and the period of hospitalization in these cases.

Diabetic patients with carbuncles should be treated as emergency cases hospitalized immediately have careful management of their diabetes and receive daily injections of penicillin. When the carbuncle is so

advanced that penicillin fails to cause complete disappearance and leaves a small central area of necrosis, it may be treated by a small incision followed by packing with gauze for 1 or 2 days. Small carbuncles that fail to resolve completely are best treated by complete excision and early skin grafting. Extensive operations such as were previously done for carbuncles are necessary only in the badly neglected cases. Parenteral administration of penicillin is superior to local or oral use.

The mortality of major and minor leg amputations in diabetic patients between 1933 and 1942 before the use of sulfonamides or penicillin was 9.7 per cent (1,036 cases) as compared to 2.6 per cent (239 cases) since the use of antibiotic and chemical therapy. This remarkable improvement is attributed solely to the increasing ability to eliminate infection.

The supracondylar type of amputation is the safest and easiest; the lower leg type and the Gritti-Stokes operations being reserved for selected cases. Gullotine amputation is indicated for patients in poor condition or those with extensively spreading infection but it is now rarely required.

When infection can be controlled in the diabetic patient a more conservative operation can be done. The transmetatarsal amputation is now used, but formerly it was not feasible because of the danger of invasive local infection and septicemia. Seventy-five metatarsal amputations have been done in the past 2 years, in 11 cases they failed and in 1 case the patient died of coronary disease. Indications for this type of operative procedure are not yet clear. Occasionally a small area of necrosis occurs on the dorsal flap. The importance of penicillin is recognized when one realizes that in 75 routine cultures from this group the *Staphylococcus aureus* was present in pure cultures in 11 cases and in combination with other organisms, usually streptococci, in 41 instances. Experience has shown that amputation at the metatarsal level is practical and safe with the use of penicillin and gives a better functional result than when done at a higher level in the leg. The author estimates that from 10 to 15 per cent of this group would have required amputation at a higher level prior to the use of penicillin.

A further advantage in technique is the suture of the operative site leaving only a small part open for drain-

age following removal of one or several toes when the foot is split longitudinally. This results in a smaller scar and decreases the healing time.

Proximal spinal anesthesia is best, and no justification is found for the use of refrigeration anesthesia. Preoperative sedation is not given to these patients since it is believed unnecessary and at times dangerous.

C. FATHALLAH KUTUB, M.D.

Cordier, G. and Demirleau, J.: The Use of Animal Plasma or Serum in Man. Universal Detoxified Plasma or Serum (L'utilisation du plasma ou serum animal chez l'homme. Plasma ou serum universel detoxique) *Presse med.*, 446, 54, 833.

During the last war the supply of human plasma or serum for transfusion presented a difficult problem for the French Army fighting in Tunisia as the Mohammedan soldiers refused to donate blood. Based on an article by Donald Edwards in the *British Medical Journal* the author developed a method of using animal plasma for transfusion purposes. Bovine plasma was used as it has the greatest similarity to human plasma in its protein content. The blood was drawn from living cattle which were at the slaughter house.

In order to detoxify the plasma, the globulins have to be removed from the blood as the antibodies attached to the globulins seem to be the cause of untoward accidents in transfusion. The citrated blood is kept for 3 days at room temperature in the dark, then centrifuged for 15 minutes. The plasma is then filtered through cotton and muslin, 0.3 per cent formalin and 0.34 per cent ammonia are added, and the serum is kept in a water bath at 74 C. for 30 minutes.

The author's experiences are still rather limited (about 100 cases) but the results were most encouraging. In only 3 cases were reactions observed with chills and hyperpyrexia. The amount of transfused plasma averaged 400 c.c. although some patients received as much as 1,000 c.c. without any reaction. In several cases the transfusion was repeated after 10 to 15 days without any signs of anaphylaxis. It is important to make the transfusion very slowly.

 maternity 349
 Forceps, Study of supination and pronation with especial
 reference to treatment of fractures of 578

Foreign body, In and in relation to the thoracic blood vessels and heart migratory within blood vascular system, 54 management of intracocular in military practice, 122 surgically removed embolus due to, in pulmonary artery 435 intraocular: 72 cases in B.L.A., 525

Fractures, Of inferior maxilla and indications for new surgical method of treating: osteosynthesis with Kirschner wire, 9 of upper end of radius, 72 of elbow with particular regard to distal end of humerus, 175 multiple, in long bones of infants suffering from chronic subdural hematoma, 76 articular and nerve complications following epitracheal 276, of carpal scaphoid bone analysis of 66 cases, 277 of neck of femur 277 late complications of of neck of femur treated surgically 277 intra-articular in upper end of tibia and lower end of femur 278 dislocation and dislocation with, of spinal column, 33 orthopedic surgery in European theater of operations, 372 subtrochanteric osteotomy for ununited, of neck of femur 368 anterior transarticular route in surgical repair of supracondylar of humerus in children, 368 of mandible, 47 of malar zygomatic compound treatment by improved methods and myoplasty 47 operation for nonunion of of carpal navicular 477, study of aspiration and pronation with especial reference to treatment of forearm, 578, end-results of bone grafting for nonunion of carpal navicular 579 stable osteosynthesis personal experience with Kuestcher's method, 579 accidents in childhood, 586

Friedmann's reaction, Biologic reaction in cases of tumor of testicle, 85

Frontal bone, Eosinophile granuloma of 305

Frostbite sustained in war 384

Funnel chest, Surgical treatment of, 49

Forunculosis, Mechanism of infection in chronic recurrent staphylococcal diseases, special clinical bacteriological investigation of and its complications, 580

GALL bladder, Nonsurgical cholangiography in lithiasis of, 68 cholecystitis with perforation, 50 treatment of cholecystitis, 25 clinical and pathohistological aspect of acute cholecystitis comparative investigation 445 etiology of cholecystitis, 554 clinical study of normal and pathological motor activity of preliminary report, 504

Gangrene, Two additional cases of, of limbs of enous origin, 270

Gas, Embolism of brain due to good effect of intra enous injection of novocain, 38

Gas gangrene, Collective review, 507

Gastrostomy, Subtotal, for duodenal ulcer 328

Gastritis, Chronic its course and significance, 245

Gastrointestinal tract, Nutritional abdominal allergy from surgical standpoint, 56 treatment of cardiopneum by esophagogastrotomy 27 treatment of patients with achalasia by esophagogastrotomy, 57 suppurative perisplenicitis, 64 bleeding in, in hereditary hemorrhagic telangiectasia historical review and case report with gastroscopic findings and rolin therapy 43 approach to resection of esophagus and gastric cardia, 143 resection of stomach, 43 study of peptic ulcer 44 aftermath of perforated peptic ulcer 144 histological diagnosis of appendicitis, 144 mediastinal tumors and cysts, collective review 93 antitretic cytotoxic serum of Bogenmoltz in treatment of diseases of 244, problems in etiology of peptic ulcer resistance of to digestive action of its own secretions, 246 prolapse of rectum, 248 new technique for temporary cecostomy 333 normal appendices in ooc pyndec

tomies, 334 gastrocolic fistula, clinical and experimental study 440 relation between appendical carcinoma and appendicitis, 442 symposium on bleeding of diagnostic and therapeutic considerations 517 roal genological examination in patients with bleeding from, 547 analysis of peptic ulcer in South Australia, based on study of 1,037 reports, 548, conservative treatment of acute perforated peptic ulcer 548 effectiveness of parenterally administered "enterogastrol" in prophylaxis of recurrences of experimental and clinical peptic ulcer 549 surgical aspects of hemorrhage from peptic ulcer 549 appendicitis; review of 536 cases at Clodinnati General Hospital, 551 acute appendicitis in aged, 551

Gause, Absorbable, in bone surgery 80 report of clinical trial of oxidized, in 7 thoracoplasties, 319

Gelatin, Clinical and experimental observations on use of sponge or foam of 388 sponge for control of hemorrhage, 403 studies on use of sponge or foam of as hemostatic agent in experimental liver resections and injuries to large veins, 505

Gelatinous disease of peritoneum, 328

Genital organs (female) Torsion of fallopian tube, 71, endometriosis adenoma of, 72 associated neoplasms of genitotummary spheres, 72 results of salpingostomy at Public Maternity Hospital, Stockholm, 931-1044, 5 surgery for female sterility 52 unilateral metastases from tumors of, 55 treatment of apical discharge, 56 results in treatment of gynecologic and obstetric conditions with Bogenmoltz' antitretic cytotoxic serum (ACS) 256; Halben's operation anatomical study of vesicovaginal fascia, 341 study of pathological associations between internal, and appendix, 345 intraperitoneal hemorrhages of genital origin, not including ectopic pregnancy 345 clinicostatistical study of 56 cases of hydatidiform mole, 346; gonocytoma, 347 operative procedure for repair of urethrovaginal fistula, 451; conservative surgery in endometriosis, 45 arthroblastoma-androblastoma, 452 surgical treatment of prolapse of uterus, 557, surgical treatment of myomas of uterus, 557 particular reference to myomectomy, 557 neoplasms of broad ligament critical review of literature with report of 3 cases, 559, hemoperitoneum from ectopic chorionepitheloma, 560 relation of tumors of small bowel to, 56

Genital organs (male) Value of urethrography in tuberculous of, 84 benign prostatic obstruction, 85 biologic reaction in 3 cases of tumor of testicle Friedmann's reaction, 85 fertility in operatively treated and untreated cryptorchidism, 63 non-specific acute epididymitis, 66 male infertility 268, male chirocitic, 268, gonocytoma, 347, arthroblastoma-androblastoma, 452 bumps orchitis, 450

Genitourinary surgery Oxidized cellulose (absorbable hemostatic gauze cellulose acid) its use in, 270

Genitourinary tract, Unnecessary abdominal operations for pathological lesions of 340 injuries to, in European theater of operation, 359

Gland, Bilateral mixed tumors of submaxillary 42

Glaucosene, Use of diisopropyl fluorophosphate (DFP) in treatment of, 24

Glycogen, Observations on carbohydrate metabolism during prolonged pentothal anesthesia in dogs, blood sugar and liver 187

Golter, Exophthalmic, in males, 27 mediastinal tumors and cysts, collective review, 93 lymphadenoid, its differentiation from chronic thyroiditis, 228 studies on 2 sporadic cretinous brothers with remarks on relation of hyperplasia to neoplasia, 423 malignant, 553

SUBJECT INDEX—ABSTRACTS—VOLUME 84

xi

- Gonococci, Peritonitis due to, of upper part of abdomen in young women (phlebotic reaction or subcostal syndrome of Stajano Fitzhugh-Curtis syndrome) report of cases of 3 patients treated successfully with penicillin and summary of literature, 154
- Gooeytoma, 347
- Grafting, Surgical principles of split thickness skin, 484 and results of bone, for nonunion of carpal navicular
- Grafts, Of skin for burned dorsum of hand, 283 study of late of nerve homographs in man, 314 repair of war wounds of bulbous and membranous urethra with split thickness skin, and penicillin, 354 tendon and mortise, for bridging metacarpal defects due to gunshot wounds, 365 repair of avulsion wounds of hands and feet by flap technique, 381 further reports on use of composite free of skin and cartilage from ears, 431 pseudarthrosis with bone loss treated with flexible bone, and intra medullary wire, 474, free transplants of skin and bone of thickness for split skin 586
- Gumoma, Eosinophilic, of frontal bone, 305 ominous manifestations of eosinophilic report of 9 cases, 472 eosinophilic, of bone, 574
- Graves' disease, What has [thiourea] taught us about pathologic physiology of, 531
- Gynecomastia, Pseudoembolic phlebitis, 374
- Gynecology, Kidney, cysts in field of, 340 importance of pyruvate, and obstetrics, 453, present status of trans fusion of whole blood and its derivatives in obstetrics and, 455 phlebotomy and thrombophlebitis in Gynecostasis, Mastectomy for through semicircular in uterine incision, 317
- H**
- HALBAN'S operation, Value of in treatment of genital study of vesicovaginal fascia, 341 anatomic (Hahn rigidus, Halbus valgis) 341
- Halgren, Antiseptics and dissection in surgery collective review 107
- Hatch, Bone surgery of, 80 early covering of extensive traumatic deformities of, and foot, 182 skin grafting for bridging metacarpal defects due to gunshot wounds, 365 repair of avulsion wounds of hands and feet by flap graft technique, 381 rehabilitation of injured, 386
- Head, Visual disturbances associated with injuries of 223 double, 308
- Harelip, Surgical deformity of wrist and, 370
- Hemangioma, Multiple fractures in long bones of infants suffering from chronic subdural, 376 experimental study of aneurysm, 312, experiences with operative treatment of Hemoperitonium, Rare case of, from 1941 to 1946 479
- Hemophilia, Pseudo-hemophilia, 376 pseudohemophilia case study 377
- Hemorrhage, Freedom of surgical arrest of massive in peptic ulcer 59 prevention of complications in biliary surgery by vitamin K, 140 surgical treatment of biliary epistaxis in relation to ethmoidal arteries, 315 surgical treatment of bleeding peptic ulcer 349 intraperitoneal history of in peptic ulcer 441 non-gravid ovarian, caused by rupture of fertilized ovum at level of ovary 454 gelatin sponge for control of 493 2 cases of allergic reaction with diathesis for follow up roentgen treatment, 467 absorbent gauze, riboflavin, thiamin, and nicotinic acid in relation to severe injury and infection in human, 505 symposium on gastronomic bleeding, diagnostic and therapeutic considerations of gastrointestinal bleeding 541 roentgenologically administered "enterogastroscope" in prophylaxis of recurrences of experimental and clinical peptic ulcer 549
- Hemostasis, Clinical and experimental observations on use of gelatin sponge or foam 288 reaction of tissue to, and fate of oxidized cellulose in peritoneal cavity of dog 307 after adrenalectomy 493 studies on use of gelatin sponge or foam as agent for in experimental liver reactions and injuries to large veins, 503
- Hemothorax, Walled off by fibrous deposit impenetrable 132 massive organizing, 241
- Hepatic Subcutaneous, in anticoagulation therapy 97 in venous thrombosis, 241
- Hernia, Important dividing wall between caudal, and prolapse of abdominal or pelvic viscera, 72 why recurs, 245 Spigel's, 243 inguinal, unpredictable results, 440
- Hernia diaphragmatic granuloma and brain, 533
- Hip, Experiences with Brinllo tachoformal arthrodesis, 91 treatment of congenital dislocation of 92 infant epiphyseal dislocation of its diagnosis and treatment, 168 route of internal access to 276 treatment of chronic congenital dislocation of 305 reduction and arthrodesis of old unilateral congenital dislocations of 376
- Hirschsprung's disease, Management of megacolon, 443 infants, 570
- Histamine, Irradiation sickness effect of treated with benadryl, 100
- Hodgkin's disease, Mediastinal tumors and cysts collective review 195
- Hormones, Influence of some sexual and of cholesterol on productive phenomena in uterus and in mammary glands, 557 influence of ACTH, upon hepatic lesions produced by 2 acetaminofluorene 399 quantitative anal
- wounds of 237 resection by massage of 485 size of in routine chest films, 496 determination of frontal plane area from product of long and short diameters of Heart Antiseptics and dissection in surgery collective review 107
- Hemangioma, Mediastinal tumors and cysts collective review 195
- Hematomas, Multiple fractures in long bones of infants suffering from chronic subdural, 376 experimental study of aneurysm, 312, experiences with operative treatment of Hemoperitonium, Rare case of, from 1941 to 1946 479
- Hemophilia, Pseudo-hemophilia, 376 pseudohemophilia case study 377
- Hemorrhage, Freedom of surgical arrest of massive in peptic ulcer 59 prevention of complications in biliary surgery by vitamin K, 140 surgical treatment of biliary epistaxis in relation to ethmoidal arteries, 315 surgical treatment of bleeding peptic ulcer 349 intraperitoneal history of in peptic ulcer 441 non-gravid ovarian, caused by rupture of fertilized ovum at level of ovary 454 gelatin sponge for control of 493 2 cases of allergic reaction with diathesis for follow up roentgen treatment, 467 absorbent gauze, riboflavin, thiamin, and nicotinic acid in relation to severe injury and infection in human, 505 symposium on gastronomic bleeding, diagnostic and therapeutic considerations of gastrointestinal bleeding 541 roentgenologically administered "enterogastroscope" in prophylaxis of recurrences of experimental and clinical peptic ulcer 549
- Hemostasis, Clinical and experimental observations on use of gelatin sponge or foam 288 reaction of tissue to, and fate of oxidized cellulose in peritoneal cavity of dog 307 after adrenalectomy 493 studies on use of gelatin sponge or foam as agent for in experimental liver reactions and injuries to large veins, 503
- Hemothorax, Walled off by fibrous deposit impenetrable 132 massive organizing, 241
- Hepatic Subcutaneous, in anticoagulation therapy 97 in venous thrombosis, 241
- Hernia, Important dividing wall between caudal, and prolapse of abdominal or pelvic viscera, 72 why recurs, 245 Spigel's, 243 inguinal, unpredictable results, 440
- Hernia diaphragmatic granuloma and brain, 533
- Hip, Experiences with Brinllo tachoformal arthrodesis, 91 treatment of congenital dislocation of 92 infant epiphyseal dislocation of its diagnosis and treatment, 168 route of internal access to 276 treatment of chronic congenital dislocation of 305 reduction and arthrodesis of old unilateral congenital dislocations of 376

 ULCER Problem of surgical arrest of massive hemorrhage in peptic, 59
 study of time of healing of peptic in series of 69 cases of duodenal and gastric craters, 60
 morphology and variations of duodenal vasculature relationship to problems of duodenal vasculature treatment duodenal stump bleeding, peptic, and injury to common duct, 60
 surgical treatment of peptic complications of chronic non-specific colitis with, 64
 study of peptic, 144
 aftermath of perforated peptic, 144
 peptic, 144
 aftermath of perforated peptic, 144
 localized gastroduodenal, 245
 problems in etiology of peptic resistance of gastrointestinal tract to digestive action of its own secretions, 245
 necrosis and, of intestinal wall in simple intestinal obstruction 246
 subtotal gastrectomy for duodenal 318
 surgical treatment of bleeding peptic, 320
 late results in treatment of colitis with, 332
 tropical, and cutaneous diphtheria, 368
 peptic, of esophagus report of patient with 10 year follow up 435
 pathogenesis of 441
 history of hemorrhage in peptic, 441
 effectiveness of parenterally administered "enterogastrol" in prophylaxis of recurrence of experimental and clinical peptic, 540
 study of peptic, in South Australia, based on analysis of 1037 case reports, 543
 conservative treatment of acute perforated peptic, 548
 surgical treatment of hemorrhage from peptic, 548
 insulin test for presence of intact nerve fibers after vagal operations for peptic, 549
 simple jejunal 550, primary closure of decubitus, 584
 perforation of duodenal, during roentgen examination, 593
- U**
 Ultraviolet light, Antidiarrhea and disinfection in surgery collective review 107
- U**
 Umbilical cord Anatomic peculiarities of human and their clinical significance 402
- U**
 Umbilicus, Metastases in, from tumors of female genitalia 155
- U**
 Ureter Retrograde movement of calculus in, 83
 histopathological and pathogenic study of chronic periglomerular with special regard to lesions of terminal end of 84
 unique case of submucosal epithelial nests in and renal pelvis, 204
 instrumental perforation of 354
 vesico-ureteral reflux 465
 belt for compression of 568
 coverage of hypoplasia and fistula of 163
 loss of diagnostic sign, 205
 repair of war wounds of bulbous and membranous, with split thickness skin grafts and penicillin 354
 female and relation to upper urinary tract infections 350
 traumatic rupture of bladder and posterior 4 observations, 406
- U**
 Urethritis, Abacterial pyuria presenting as 266
 significance of chronic, in women, 559
- U**
 Uthography Value of in male genital tuberculosis, 84
